This report is based on research conducted by the Brown Evidence-based Practice Center (EPC) under contract to the Agency for Healthcare Research and Quality (AHRQ), Rockville, MD (Contract No. 290-2012-00012-I). The findings and conclusions in this document are those of the authors, who are responsible for its contents; the findings and conclusions do not necessarily represent the views of AHRQ. Therefore, no statement in this report should be construed as an official position of AHRQ or of the U.S. Department of Health and Human Services.

**None of the investigators have any affiliations or financial involvement that conflicts with the material presented in this report.**

The information in this report is intended to help health care decisionmakers—patients and clinicians, health system leaders, and policymakers, among others—make well-informed decisions and thereby improve the quality of health care services. This report is not intended to be a substitute for the application of clinical judgment. Anyone who makes decisions concerning the provision of clinical care should consider this report in the same way as any medical reference and in conjunction with all other pertinent information, i.e., in the context of available resources and circumstances presented by individual patients.

This report is made available to the public under the terms of a licensing agreement between the author and the Agency for Healthcare Research and Quality. This report may be used and reprinted without permission except those copyrighted materials that are clearly noted in the report. Further reproduction of those copyrighted materials is prohibited without the express permission of copyright holders.

AHRQ or U.S. Department of Health and Human Services endorsement of any derivative products that may be developed from this report, such as clinical practice guidelines, other quality enhancement tools, or reimbursement or coverage policies, may not be stated or implied.

This report may periodically be assessed for the currency of conclusions. If an assessment is done, the resulting surveillance report describing the methodology and findings will be found on the Effective Health Care Program Web site at [www.effectivehealthcare.ahrq.gov](http://www.effectivehealthcare.ahrq.gov). Search on the title of the report.

## Preface

The Agency for Healthcare Research and Quality (AHRQ), through its Evidence-based Practice Centers (EPCs), sponsors the development of systematic reviews to assist public- and private-sector organizations in their efforts to improve the quality of health care in the United States. These reviews provide comprehensive, science-based information on common, costly medical conditions, and new health care technologies and strategies.

Systematic reviews are the building blocks underlying evidence-based practice; they focus attention on the strength and limits of evidence from research studies about the effectiveness and safety of a clinical intervention. In the context of developing recommendations for practice, systematic reviews can help clarify whether assertions about the value of the intervention are based on strong evidence from clinical studies. For more information about AHRQ EPC systematic reviews, see [www.effectivehealthcare.ahrq.gov/reference/purpose.cfm](http://www.effectivehealthcare.ahrq.gov/reference/purpose.cfm).

AHRQ expects that these systematic reviews will be helpful to health plans, providers, purchasers, government programs, and the health care system as a whole. Transparency and stakeholder input are essential to the Effective Health Care Program. Please visit the Web site ([www.effectivehealthcare.ahrq.gov](http://www.effectivehealthcare.ahrq.gov)) to see draft research questions and reports or to join an email list to learn about new program products and opportunities for input.

If you have comments on this systematic review, they may be sent by mail to the Task Order Officer named below at: Agency for Healthcare Research and Quality, 5600 Fishers Lane, Rockville, MD 20857, or by email to [epc@ahrq.hhs.gov](mailto:epc@ahrq.hhs.gov).

## Key Informants

In designing the study questions, the EPC consulted several Key Informants who represent the end-users of research. The EPC sought the Key Informant input on the priority areas for research and synthesis. Key Informants are not involved in the analysis of the evidence or the writing of the report. Therefore, in the end, study questions, design, methodological approaches, and/or conclusions do not necessarily represent the views of individual Key Informants.

Key Informants must disclose any financial conflicts of interest greater than \$10,000 and any other relevant business or professional conflicts of interest. Because of their role as end-users, individuals with potential conflicts may be retained. The TOO and the EPC work to balance, manage, or mitigate any conflicts of interest.

The list of Key Informants who provided input to this report follows:

Anthony Chow, M.D.  
Division of Infectious Diseases  
University of British Columbia Vancouver  
Hospital  
Vancouver, BC, Canada

Tyler Hughes, M.D.  
McPherson Hospital  
McPherson, KS

Douglas Katz, M.D., FACR  
Vice Chairman of Research and Education  
Winthrop Radiology Associates  
Winthrop-University Hospital, Department  
of Radiology  
Director of Body CT, Winthrop-University  
Hospital  
Mineola, NY

Anupam Kharbanda, M.D., M.Sc.  
Director of Research, Emergency Services  
Associate PEM Fellowship Director  
Department of Pediatric Emergency  
Medicine  
Children's Hospitals and Clinics of  
Minnesota  
Minneapolis, MN

Susan Promes, M.D.

## Technical Expert Panel

In designing the study questions and methodology at the outset of this report, the EPC consulted several technical and content experts. Broad expertise and perspectives were sought. Divergent and conflicted opinions are common and perceived as healthy scientific discourse that results in a thoughtful, relevant systematic review. Therefore, in the end, study questions, design, methodologic approaches, and/or conclusions do not necessarily represent the views of individual technical and content experts.

Technical Experts must disclose any financial conflicts of interest greater than \$10,000 and any other relevant business or professional conflicts of interest. Because of their unique clinical or content expertise, individuals with potential conflicts may be retained. The TOO and the EPC work to balance, manage, or mitigate any potential conflicts of interest identified.

The list of Technical Experts who provided input to this report follows:

Anthony Chow, M.D.  
Division of Infectious Diseases  
University of British Columbia Vancouver  
Hospital  
Vancouver, BC, Canada

Tyler Hughes, M.D.  
McPherson Hospital  
McPherson, KS

Douglas Katz, M.D., FACR  
Vice Chairman of Research and Education  
Winthrop Radiology Associates  
Winthrop-University Hospital, Department  
of Radiology  
Director of Body CT, Winthrop-University  
Hospital  
Mineola, NY

Anupam Kharbanda, M.D., M.Sc.  
Director of Research, Emergency Services  
Associate PEM Fellowship Director  
Department of Pediatric Emergency  
Medicine  
Children's Hospitals and Clinics of  
Minnesota  
Minneapolis, MN

Susan Promes, M.D.  
University of California San Francisco  
School of Medicine  
San Francisco, CA

David Rahn, M.D.  
University of Texas Southwestern  
Dallas, TX

Martin P. Smith, M.D.

and Surgical Critical Care  
Boston, MA

## Peer Reviewers

Prior to publication of the final evidence report, EPCs sought input from independent Peer Reviewers without financial conflicts of interest. However, the conclusions and synthesis of the scientific literature presented in this report do not necessarily represent the views of individual reviewers.

Peer Reviewers must disclose any financial conflicts of interest greater than \$10,000 and any other relevant business or professional conflicts of interest. Because of their unique clinical or content expertise, individuals with potential nonfinancial conflicts may be retained. The TOO and the EPC work to balance, manage, or mitigate any potential nonfinancial conflicts of interest identified.

The list of Peer Reviewers follows:

Roland E. Andersson, M.D., Ph.D.  
Linköping University  
Linköping, Sweden

Richard Bachur, M.D.  
Harvard Medical School  
Boston, MA

Esther H. Chen, M.D.  
University of California, San Francisco/San  
Francisco General Hospital  
Department of Emergency Medicine  
Associate Professor of Emergency Medicine  
San Francisco, CA

Anthony Chow, M.D.  
Division of Infectious Diseases  
University of British Columbia Vancouver  
Hospital  
Vancouver, BC, Canada

Andrea S. Doria, M.D., Ph.D., M.Sc.  
The Hospital for Sick Children  
Toronto, ON, Canada

Sherif Emil, M.D., C.M.  
Pediatric General and Thoracic Surgery  
The Montreal Children's Hospital  
McGill University Health Centre  
Montreal, QC, Canada

Tyler Hughes, M.D.  
McPherson Hospital

# Diagnosis of Right Lower Quadrant Pain and Suspected Acute Appendicitis

## Structured Abstract

**Background.** The reliable identification of patients with abdominal pain who need surgical intervention for acute appendicitis can improve clinical outcomes and reduce resource use. The test performance and impact on outcomes of alternative diagnostic strategies are unclear.

**Study eligibility criteria.** We searched PubMed<sup>®</sup>, Embase<sup>®</sup>, the Cochrane Central Register of Controlled Trials, and the Cumulative Index to Nursing and Allied Health Literature<sup>®</sup> to identify primary research studies meeting our criteria for cohort studies that reported information on test accuracy for the diagnosis of acute appendicitis or harms, and for comparative studies (randomized or nonrandomized) that reported information on patient-relevant outcomes and resource use (last search, August 6, 2014, for PubMed; August 12, 2014, for all other databases).

**Study appraisal and synthesis methods.** A single investigator extracted data from each study and a second investigator verified extracted data from comparative studies; we also extracted data in duplicate for a sample of noncomparative studies. We performed Bayesian meta-analyses to estimate summary test performance using random-effects models; data on other outcomes were synthesized qualitatively. We also assessed the strength and applicability of the evidence.

**Results.** Information on the test performance of diagnostic tests was available from 903 studies: clinical symptoms and signs (137 studies), laboratory tests (217 studies), imaging tests (519 studies), multivariable diagnostic scores (127 studies), and diagnostic laparoscopy (55 studies). Trials directly comparing diagnostic tests were too heterogeneous to support definitive conclusions; therefore, most of our results pertain to the test performance of individual tests. Clinical symptoms and signs, and laboratory tests had relatively low sensitivity and specificity when used in isolation. Their combination in multivariable scores performed somewhat better; however, the most studied scores were developed before the widespread use of imaging, thus lessening the applicability of their results to current practice. Computed tomography (CT) had high sensitivity (summary estimates ranging from 0.96 to 1) and specificity (0.91 to 1) in all populations of interest to this report; magnetic resonance imaging (MRI) had high sensitivity (0.94 to 1) but appeared to have variable specificity (0.86 to 1), mainly because of the smaller number of studies, which focused on its use for pregnant women. In adult populations, ultrasound (US) had lower sensitivity (0.85) and specificity (0.90) than CT and MRI, and produced more nondiagnostic scans. In children, the specificity of US was similar to that of CT (0.91 vs. 0.92), but CT had greater sensitivity (0.89 vs. 0.96); these results were based on a large number of studies (85 for US and 34 for CT). In the same patient population, MRI had a specificity of 0.96 and sensitivity of 0.97, but data were derived from only seven studies. Among pregnant women CT, MRI, and US had similar specificity (0.91, 0.98, and 0.95, respectively), but CT and MRI had higher sensitivity than US (0.99, 0.98, and 0.72, respectively). Information on diagnostic test performance among the elderly was limited. Studies of test performance were deemed to be at moderate risk of bias, mostly because of concerns about differential and incomplete verification.

Information on patient-relevant outcomes and resource use was available from a small number of trials with moderate risk of bias that assessed heterogeneous comparisons between various tests and nonrandomized studies that did not appropriately adjust for potential confounding factors. Only a few studies reported information on harms, leading to concerns about selective outcome reporting. Therefore, no definitive conclusions could be drawn about patient-relevant outcomes or harms.

**Limitations.** Patient-level data were unavailable, and information about study- or population-level characteristics was too limited to allow the identification of modifiers of test performance, patient-centered outcomes, or harms. Studies reported adverse events incompletely and did not provide details of outcome ascertainment methods.

**Conclusions.** The literature on the diagnosis of acute appendicitis is large but consists almost exclusively of studies assessing the performance of individual tests. The evidence on individual tests indicates that imaging tests have adequate test performance, while clinical symptoms and signs and laboratory tests used in isolation have lower discriminatory capacity. The evidence is largely insufficient to support conclusions about comparative effectiveness for clinical outcomes because studies assessing more than two test strategies on the same population are few and have evaluated different test comparisons. More research is needed to evaluate the comparative performance and effectiveness of individual tests, test combinations, and integrated diagnostic algorithms; to identify potential modifiers; and to evaluate the impact of testing strategies on patient-relevant outcomes, resource use, and harms. Decision and simulation models using information from this review could inform the design of future studies and guide decisionmaking.

# Executive Summary

## Background

Abdominal pain is a common presenting symptom for patients seeking care at emergency departments, with approximately 3.4 million expected cases per year in the United States.<sup>1</sup> Appendicitis is a frequent cause of abdominal pain and occurs in approximately 8 to 10 percent of the population over a lifetime.<sup>2,3</sup> Appendicitis has its highest incidence between the ages of 10 and 30 years. The ratio of incidence in men and women is 3:2 through the mid-20s and then equalizes after age 30. Appendicitis is the most common abdominal surgical emergency, with over 250,000 appendectomies performed annually in the United States. The risk of acute appendicitis in pregnant women is not much lower than that of the general population, making appendicitis the most common nonobstetric emergency during pregnancy.<sup>4-7</sup> Untreated appendicitis can lead to perforation of the appendix, which typically occurs within 24 to 48 hours of the onset of symptoms.<sup>8</sup> Perforation of the appendix can cause intra-abdominal infection, sepsis, intraperitoneal abscesses, and rarely death.<sup>4</sup> In order to avoid the sequelae of perforated appendicitis, a low percentage of “negative” appendectomies (i.e., removing a normal noninflamed appendix in patients mistakenly diagnosed with appendicitis) is generally accepted from a surgical standpoint.

Clinical symptoms and signs suggestive of appendicitis include a history of central abdominal pain migrating to the right lower quadrant (RLQ), anorexia, fever, and nausea/vomiting. On examination, RLQ tenderness, along with “classical” signs of peritoneal irritation (e.g., rebound tenderness, guarding, rigidity, referred pain), may be present. Other signs (e.g., the psoas or obturator signs) may help the clinician localize the inflamed appendix.<sup>9-11</sup> However, many patients have a less typical presentation, necessitating the use of laboratory or imaging tests to establish a diagnosis. Laboratory evaluations potentially useful for the diagnosis of appendicitis include the white blood cell and granulocyte counts, the proportion of polymorphonuclear blood cells, and serum C-reactive protein.<sup>10-12</sup> Imaging tests, such as ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI), are used extensively for the diagnosis of appendicitis.<sup>13-19</sup> Imaging tests can be used alone or in combination. For example, US is sometimes used as a triage test to separate patients in whom sonography alone is adequate to establish a diagnosis from those who require further imaging.<sup>20</sup> Different factors may affect the performance of alternative tests and their impact on clinical outcomes. For example, US examination is considered to be highly operator dependent<sup>21</sup> and is technically challenging in obese patients or women in late pregnancy. CT scanning can be performed with or without the use of contrast agents, and contrast can be administered orally, rectally, intravenously, or via combinations of these routes.<sup>20</sup>

Clinical symptoms and signs, along with the results of laboratory or imaging tests, can be combined into multivariable diagnostic scores (sometimes referred to as “clinical prediction rules”) that synthesize the findings of different investigations to determine the most likely diagnosis.<sup>22</sup> In adults, the most commonly used diagnostic score for appendicitis is the Alvarado score,<sup>23</sup> which is based on eight items: pain migration, anorexia, nausea, RLQ tenderness, rebound pain, elevated temperature, leukocytosis, and shift of white blood cell count to the left.<sup>24</sup> Although the Alvarado score is also used in pediatric populations,<sup>25,26</sup> the Pediatric Appendicitis Score has been specifically developed and validated for use in children.<sup>27</sup>

Diagnostic laparoscopy is also used for the evaluation of patients with RLQ pain and suspected acute appendicitis, primarily when a diagnosis cannot be established via other means.

Although diagnostic laparoscopy is generally considered safe, studies have reported variable rates of morbidity and mortality from the procedure.<sup>28</sup>

In general these diagnostic tests are widely available in the United States. Clinical symptoms and signs can be evaluated relatively easily and inexpensively. Evidence from the National Hospital Ambulatory Medical Care Survey suggested that CT and complete blood counts are obtained in the majority of patients presenting to the emergency department with abdominal pain. The survey also showed that over time (between 1992 and 2006) the use of CT for both adults and children has increased. Over the same period, the use of the complete blood count increased in adults but decreased in children.<sup>29,30</sup> Various sources suggest that the use of US and MRI is increasing in populations in which exposure to ionizing radiation is of particular concern (e.g., children and pregnant women).<sup>31-37</sup>

As with all diagnostic tests, the modalities used in the diagnostic investigation of patients with RLQ pain affect clinical outcomes indirectly through their impact on clinicians' diagnostic thinking and decisionmaking.<sup>38</sup> More accurate and timely diagnosis of appendicitis can minimize the time to the indicated intervention (e.g., surgery), thus reducing the time patients are in pain and improving clinical outcomes (e.g., reducing the rate of perforated appendicitis and its attendant complications).<sup>39</sup> Conversely, time-consuming or unnecessary diagnostic workup (an important outcome, but hard to operationalize) may delay the indicated treatment and increase the risk of complications or result in false-positive results and more negative appendectomies. Furthermore, diagnostic testing can impact resource use for the management of patients with acute abdominal pain. For example, examination with CT may reduce length of stay by avoiding prolonged observation in cases in which a diagnosis cannot be established clinically or by eliminating the need for additional diagnostic testing.<sup>18</sup> In some cases, CT can also facilitate direct therapeutic intervention. For example, in patients with perforated appendicitis complicated by an abscess, the radiologist can not only detect but also treat the abscess by percutaneous drainage, thus avoiding the need for immediate operative intervention.

The diagnostic workup of acute appendicitis is complex because patients with acute abdominal pain of different etiologies can present with similar symptoms. Diagnosis is particularly challenging in children, women of reproductive age, pregnant women, and frail or elderly patients.<sup>20,40,41</sup> In young children (especially toddlers and preschool-age children), acute appendicitis is often diagnosed after perforation has occurred.<sup>42-44</sup> Children have a thinner appendiceal wall and less developed omentum, and thus may not readily wall off a perforation. In addition, many common childhood illnesses have symptoms similar to those of early acute appendicitis. Young children may also have difficulty communicating about their discomfort or describing their symptoms.<sup>11</sup> In addition, the use of modalities that involve ionizing radiation (e.g., CT) entails greater risks for children than for older patients.<sup>20</sup> A large proportion of women of reproductive age with appendicitis are misdiagnosed.<sup>41,45</sup> Establishing a diagnosis in this patient group can be particularly challenging because symptoms of acute appendicitis can mimic those of common gynecologic diseases (e.g., pelvic inflammatory disease, ectopic pregnancy). In pregnant women the diagnosis of suspected acute appendicitis can also be challenging because some symptoms of appendicitis (nausea and vomiting) are common in normal pregnancies and because enlargement of the uterus can alter the location of the appendix, which often moves higher and to the back.<sup>46</sup> Anatomic changes induced by pregnancy make the clinical examination of pregnant patients with abdominal pain more challenging and result in technical difficulties when using US.<sup>37,47,48</sup> Tests involving ionizing radiation (e.g., CT) are also generally avoided during pregnancy to prevent exposure of the fetus to radiation. Finally, obtaining a white blood

cell count may not be helpful in the diagnosis of acute appendicitis because leukocytosis is common during pregnancy. The elderly typically present with appendicitis in a more advanced stage because they may delay seeking care, and definitive diagnosis is sometimes delayed further because competing etiologies for abdominal pain (e.g., malignancy or diverticulitis) are considered more likely.<sup>49</sup> Therefore, the performance of diagnostic tests may be modified by patient age, and elderly and frail individuals with appendicitis have a higher complication rate and a higher risk of mortality than younger and less frail patients.

## **Rationale for Evidence Review**

Accurate testing of patients presenting with symptoms consistent with acute appendicitis to identify those who need treatment can improve clinical outcomes and reduce resource use. There is a lack of specific guidance for selecting diagnostic modalities, particularly in patient subgroups in whom the diagnosis is known to be particularly challenging (e.g., children, women of reproductive age, pregnant women, and the elderly). Existing systematic reviews typically assess a single diagnostic modality, focus almost exclusively on test performance outcomes rather than patient-relevant outcomes, and do not address factors that may modify test performance. No review to date has comprehensively examined all tests of interest or focused on comparisons between alternative strategies.

## **Key Questions**

With input from clinical experts, we developed the following Key Questions to clarify the focus of the proposed systematic review.

**Key Question 1:** What is the performance of alternative diagnostic tests, alone or in combination, for patients with RLQ pain and suspected acute appendicitis?

- a. What are the performance and comparative performance of alternative diagnostic tests in the following patient populations: children, adults, nonpregnant women of reproductive age, pregnant women, the elderly (age  $\geq 65$  years)?
- b. What factors modify the test performance and comparative test performance of available diagnostic tests in these populations?

**Key Question 2:** What is the comparative effectiveness of alternative diagnostic tests, alone or in combination, for patients with RLQ pain and suspected acute appendicitis?

- a. For the populations listed under Key Question 1a, what is the effect of alternative testing strategies on diagnostic thinking, therapeutic decisionmaking, clinical outcomes, and resource utilization?
- b. What factors modify the comparative effectiveness of testing for patients with RLQ pain and suspected acute appendicitis?

**Key Question 3:** What are the harms of diagnostic tests per se, and what are the treatment-related harms of test-directed treatment for tests used to diagnose RLQ pain and suspected acute appendicitis?

## **Methods**

We performed a systematic review of the published literature using established methods as outlined in the Agency for Healthcare Research and Quality (AHRQ) “Methods Guide for Effectiveness and Comparative Effectiveness Reviews” (Methods Guide).<sup>50</sup> We followed the reporting requirements of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA).<sup>51</sup> All key methodological decisions were made a priori. The protocol was developed with input from external clinical and methodological experts in consultation with the AHRQ Task Order Officer (TOO) and was posted online to solicit additional comments. The review’s PROSPERO registration number is CRD42013006480.

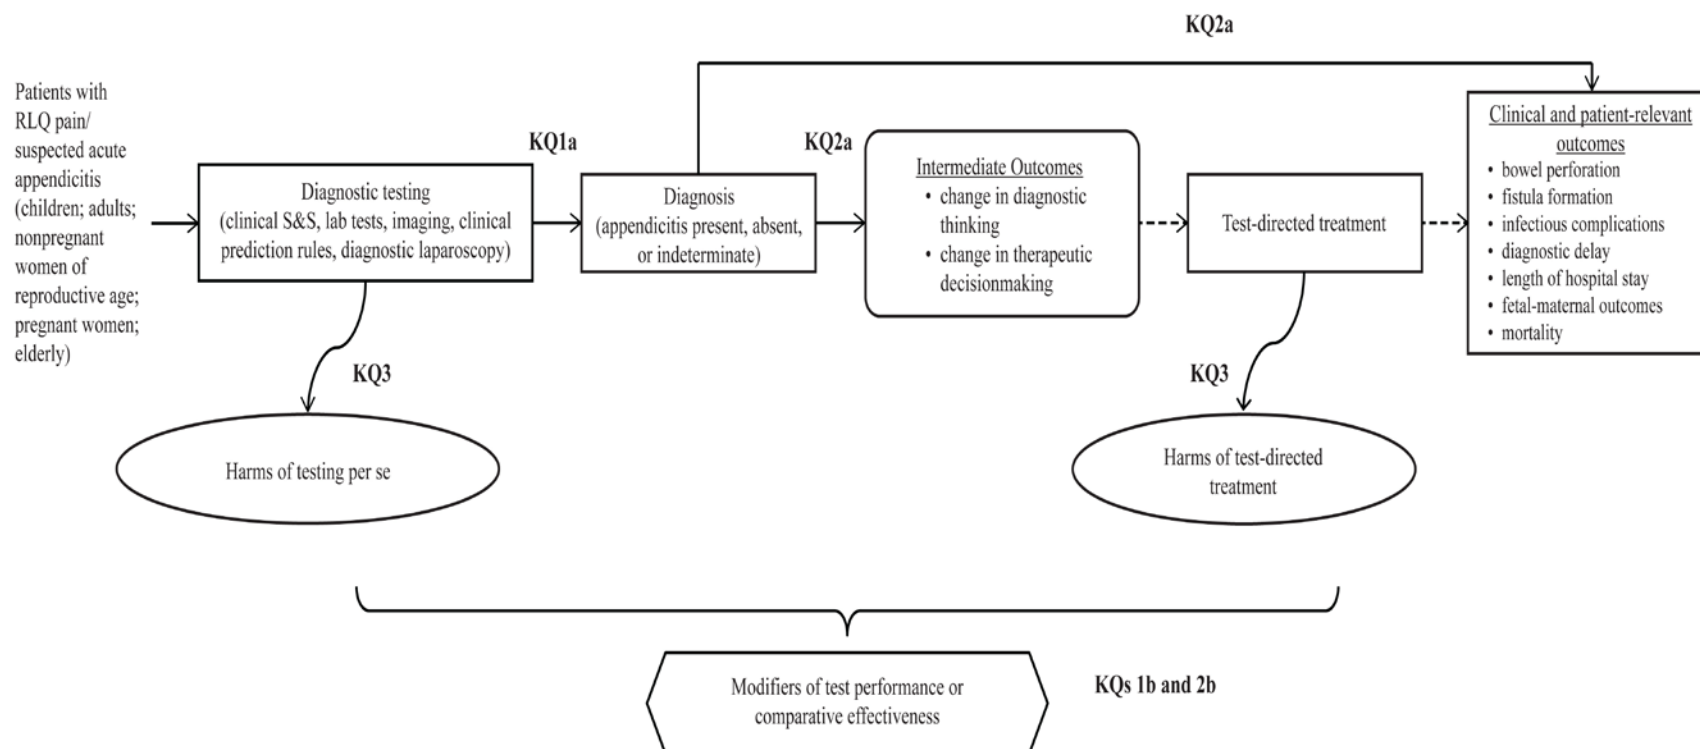

## **AHRQ TOO and External Stakeholder Input**

A panel of Key Informants, including patients and other stakeholders, gave input on the Key Questions to be examined. These Key Questions were posted on AHRQ’s Effective Health Care Web site for public comment and revised in response to comments. A Technical Expert Panel, including representatives of professional societies and experts in the diagnosis and treatment of RLQ abdominal pain and appendicitis, provided input to help further refine the Key Questions and protocol, identify important issues, and define the parameters for the review of evidence. The AHRQ TOO was responsible for overseeing all aspects of this project. Discussions among the Evidence-based Practice Center, TOO, and Technical Expert Panel occurred during a series of teleconferences and via email.

## **Analytic Framework**

We used an analytic framework (Figure A) that maps the Key Questions within the context of populations, interventions, comparators, and outcomes of interest.

**Figure A. Analytic framework**

KQ = Key Question; RLQ = right lower quadrant; S&S = symptoms and signs

## **Inclusion and Exclusion Criteria**

### **Populations and Conditions of Interest**

The population of interest for all Key Questions was patients with acute RLQ abdominal pain ( $\leq 7$  days duration) for whom appendicitis was considered in the differential diagnosis. Separate analyses were performed for children (age  $< 18$  years), adults (age  $\geq 18$  years), women of reproductive age, pregnant women, and the elderly. We initially planned to separately examine the subgroup of very young children ( $< 2$  years and 2–5 years of age); however, information for these subgroups was poorly reported and we were unable to perform these subgroup analyses.

### **Interventions**

For all Key Questions, the interventions of interest were diagnostic tests (alone or in combination) for diagnosing appendicitis, including clinical symptoms, clinical signs, laboratory tests, multivariable diagnostic scores, imaging tests, nuclear imaging studies, and diagnostic laparoscopy.

### **Comparators (Index and Reference Standard Tests)**

For all Key Questions, the comparators were alternative tests or test combinations (listed previously) or clinical observation.

### **Outcomes**

For Key Question 1, the outcome of interest was test performance, using pathology or clinical followup as the reference standard. For Key Question 2, we examined the impact of testing on diagnostic thinking, on therapeutic decisionmaking, and on patient-centered and resource use outcomes (negative appendectomy rate, bowel perforation, fistula formation, infectious complications, delay in diagnosis, length of hospital stay, fetal/maternal outcomes, and mortality). For Key Question 3, we considered adverse effects, including direct harms of testing and harms of test-directed treatment. When outcome definitions were not provided by the included studies, we adopted the terms used by the studies at face value.

### **Timing**

Studies were considered regardless of duration of followup.

### **Setting**

All health care settings were considered.

### **Study Design and Additional Criteria**

For studies assessing test performance, we used previously completed systematic reviews to identify relevant studies and obtain specific data items. We updated these reviews to include more recent studies identified through literature searches. For index tests for which no relevant systematic review of test performance meeting our selection criteria could be identified, we performed a de novo systematic review. We accepted both randomized and nonrandomized comparative studies but analyzed them separately. We included only English-language studies because our preliminary searches indicated that non-English-language studies represented a small portion of the evidence base for any given test modality and were unlikely to change conclusions.

## **Literature Search and Abstract Screening**

Appendix A in the full report describes our literature search strategies. Searches were conducted in PubMed<sup>®</sup>, Embase<sup>®</sup>, the Cochrane Central Register of Controlled Trials, and the Cumulative Index to Nursing and Allied Health Literature (CINAHL<sup>®</sup>) databases to identify primary research studies meeting our criteria (last search on August 6, 2014, for PubMed; August 12, 2014, for all other databases). We also used the PubMed search results to identify systematic reviews of the tests of interest (last search, July 31, 2013; search for systematic reviews not updated). All reviewers screened a common set of 200 abstracts, and discrepancies were discussed in order to standardize screening practices and ensure understanding of screening criteria. The remaining citations were split into nonoverlapping sets, each screened by two reviewers independently. Discrepancies were resolved by consensus involving a third investigator. We asked the Technical Expert Panel to provide citations of potentially relevant articles and identified additional studies through the perusal of reference lists of eligible studies, clinical practice guidelines, relevant reviews, and conference proceedings. The Technical Expert Panel reviewed the final list of included studies to ensure that no key publications had been missed.

## **Study Selection and Data Abstraction**

Potentially eligible citations were reviewed in full text for eligibility. A single reviewer examined each article; a second reviewer independently examined a subset of 350 articles. Disagreements were resolved by consensus involving a third reviewer. We included only English-language studies during full-text review because our preliminary searches indicated that non-English-language studies had small sample sizes and represented a small portion of the evidence base for any given test modality, so their exclusion is unlikely to have affected our conclusions. We excluded studies published exclusively in abstract form because they are typically not peer reviewed, they report only partial results, and their findings may change substantially when fully published. A detailed description of quality control measures is available in the protocol ([www.effectivehealthcare.ahrq.gov/search-for-guides-reviews-and-reports/?pageaction=displayproduct&productid=1827](http://www.effectivehealthcare.ahrq.gov/search-for-guides-reviews-and-reports/?pageaction=displayproduct&productid=1827)). The lists of included and excluded studies (organized by reason for exclusion) are in Appendix B of the full report.

Previously published reviews were used as sources of eligible studies of test performance and as sources of data for objective data elements from these studies (bibliographic information, characteristics of included populations, and counts of individuals stratified by diagnostic test result and disease status). We verified all data from studies included in previously published systematic reviews against the full text of the corresponding publications. Because of the large number of studies, a single reviewer extracted data from each eligible noncomparative study of test performance; for nonrandomized comparative studies (NRCs) and randomized controlled trials (RCTs), one reviewer extracted and a second reviewer verified the data. For RCTs, when possible, data were extracted according to the intention-to-treat principle. We verified the data extraction and risk-of-bias assessment in a random sample of 368 noncomparative test performance studies (1,487 separate estimates of test performance). Overall, agreement was excellent on items capturing information about the index and reference standard tests and numerical information on test performance. Agreement was less good for some risk-of-bias items; information on these items was reextracted for all included studies following a series of standardization exercises.

## **Assessment of the Risk of Bias of Individual Studies**

We assessed the risk of bias for each study using the assessment methods detailed by the AHRQ Methods Guide.<sup>50</sup> We used items from the updated QUADAS (Quality Assessment of Diagnostic Accuracy Studies) 2 instrument to assess the risk of bias of the diagnostic test studies included in the review.<sup>52-55</sup> For studies of other designs, we used appropriate items to assess risk of bias: for NRCSSs, we used items from the Newcastle-Ottawa scale;<sup>56</sup> for RCTs, we used items from the Cochrane Risk of Bias tool.<sup>57</sup> We rated each study as having low, intermediate, or high risk of bias on the basis of adherence to accepted methodological principles.

## **Evidence Synthesis**

We summarized the included studies qualitatively and present important features of the study populations, designs, interventions, outcomes, and results in summary tables in the full report and its appendixes. All studies evaluating the test performance of the same single index test in a similar patient population were synthesized jointly, regardless of their source (our own literature searches or previously published reviews). Analyses were performed separately for the following patient populations: children, women of reproductive age, pregnant women, and the elderly. For each comparison of interest, we judged whether the eligible studies were sufficiently similar for meta-analysis on the basis of clinical heterogeneity of patient populations and testing strategies, as well as methodological heterogeneity of study designs and outcomes reported.

When five or more sufficiently similar studies evaluated the test performance of the same test in the same population, we used a bivariate-bivariate normal meta-analysis model to obtain summary sensitivity and specificity estimates.<sup>58,59</sup> We used the model estimates to calculate summary positive and negative likelihood ratios (LRs)<sup>60</sup> and to construct summary receiver operating characteristic (ROC) curves.<sup>61,62</sup> Meta-analyses were conducted using Bayesian methods with flat (minimally informative) priors.<sup>63</sup> We assessed heterogeneity by inspecting plots of study estimates in the ROC space and by examining the posterior distribution of the between-study heterogeneity parameters (for logit-sensitivity and logit-specificity). We explored heterogeneity using subgroup and meta-regression analyses. There were not enough studies comparing the same test strategies to allow meta-analysis for clinical outcomes and resource use.

In cases in which only a subset of the available studies could be quantitatively combined, we synthesized findings across all studies qualitatively by taking into account the magnitude and direction of effects and estimates of performance.

## **Grading the Strength of Evidence and Assessing Applicability**

We followed the Methods Guide<sup>50</sup> to evaluate the strength of the body of evidence for each Key Question with respect to the following domains: risk of bias, consistency, directness, precision, and reporting bias.<sup>50,64</sup> Briefly, we assessed risk of bias (low, medium, or high) on the basis of the study design and the methodological quality of the studies. We rated the consistency of the data on the basis of the direction, magnitude, and statistical significance of all studies and made a determination. We assessed directness of the evidence on the basis of the use of surrogate outcomes or the need for indirect comparisons. We assessed the precision of the evidence on the basis of the degree of certainty surrounding each effect estimate. The potential for reporting bias was evaluated with respect to publication bias, selective outcome reporting bias, and selective analysis reporting bias. For all types of reporting bias, we made qualitative dispositions rather than performing formal statistical tests to evaluate differences in the effect sizes between more

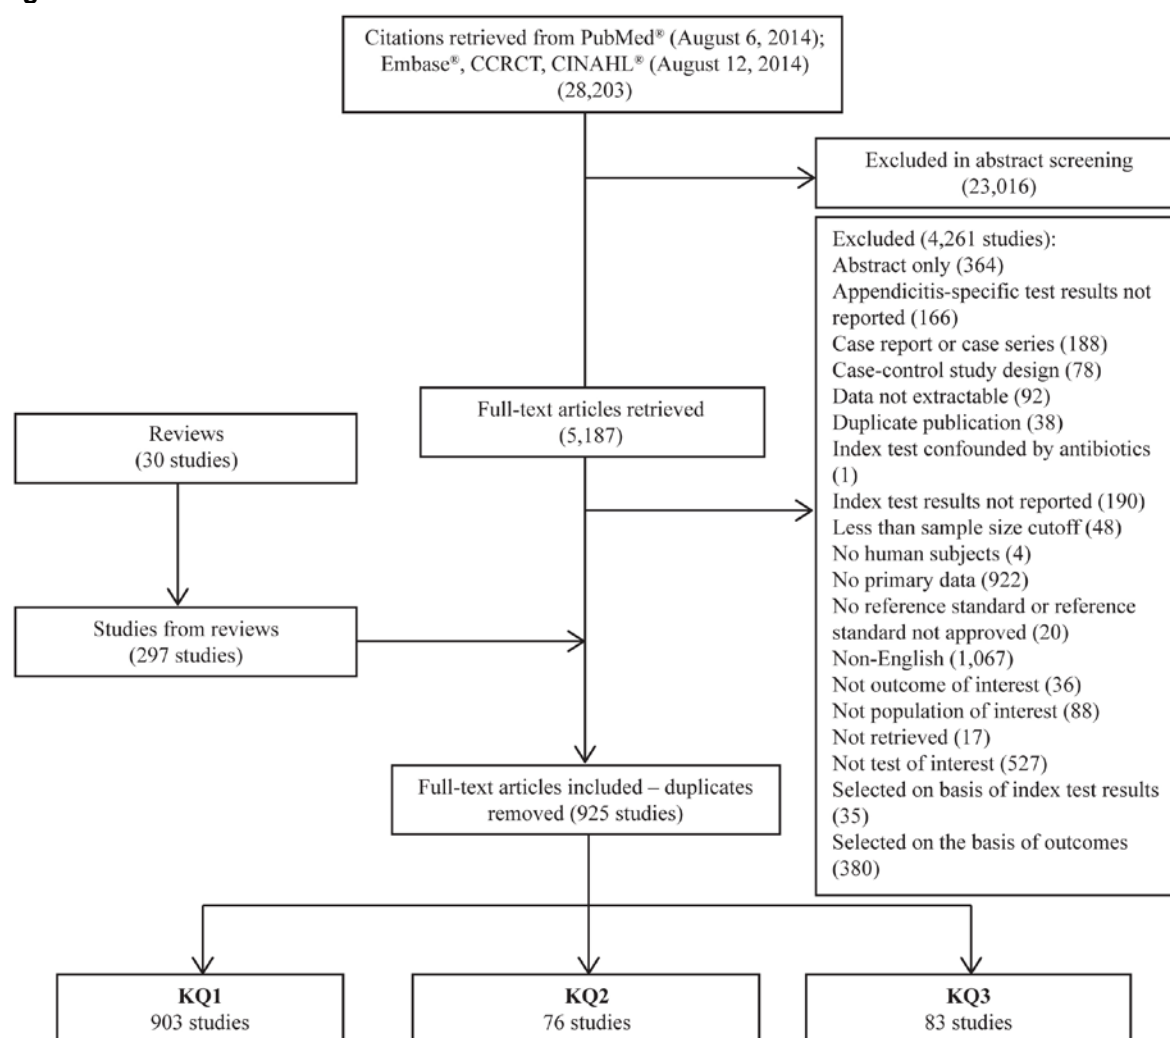

precise (larger) and less precise (smaller) studies. Instead of relying on statistical tests, we evaluated the reported results across studies qualitatively on the basis of completeness of reporting, number of enrolled patients, and numbers of observed events.<sup>63,64</sup> Judgment on the potential for selective outcome reporting bias was based on reporting patterns for each outcome of interest across studies. Finally, we rated the overall strength of the body of evidence using four levels: high, moderate, low, and insufficient.<sup>47</sup>

We followed the Methods Guide<sup>50</sup> to evaluate the applicability of included studies to patient populations of interest. We considered important population subgroups separately and evaluated the duration of symptoms before enrollment, outcomes reported, and setting of care.

## **Results**

We reviewed the full text of 5,187 publications, of which 969 were considered eligible for inclusion in the review. Figure B presents the literature flow; our search strategies are presented in Appendix A; the lists of included and excluded studies (organized by reason for exclusion) are provided in Appendix B of the full report.

**Figure B. Flow chart of included studies**

CCRCT = Cochrane Central Register of Controlled Trials; KQ = Key Question

## Key Question 1: What is the performance of alternative diagnostic tests, alone or in combination, for patients with RLQ pain and suspected acute appendicitis?

In total, 903 studies published between 1956 and 2014 met the inclusion criteria for Key Question 1. In this Executive Summary we present information on the tests that we thought were most clinically relevant on the basis of our reading of the literature, discussions with local clinical experts, and discussions with Key Informants and the Technical Expert Panel. The full report and appendixes present complete data on all tests we examined. Throughout, results for each test are presented separately for adults, children, women of reproductive age, pregnant women, and mixed populations (typically including male and female patients of all ages).

## Studies of Test Performance

In general, studies of test performance were deemed to be at moderate to high risk of bias. Estimates of test performance often appeared to be affected by characteristics of study design

that may be related to risk of bias, particularly partial and incomplete verification. In most cases, factors indicative of high risk of bias were associated with higher values of estimated test performance. These findings suggest that study conduct may have affected estimates of test performance in our meta-analyses. However, the assessment of the impact of risk of bias had to rely on information that was often poorly reported in the primary studies. Because each risk-of-bias item was examined individually and because different items may be correlated with each other and with other study characteristics that may affect test performance, we do not believe that definitive conclusions about specific items can be reached at this time.

## Test Performance of Clinical Symptoms and Signs (in Isolation)

Table A presents key test performance results for selected clinical symptoms and signs. Symptoms and signs had limited test performance when used in isolation. There was substantial heterogeneity in sensitivity and specificity for most clinical symptoms and signs.

**Table A. Summary estimates of test performance of clinical symptoms and signs for the diagnosis of acute appendicitis**

Symptom or Sign	Population	N Studies (N Affected/N Unaffected)	Sensitivity (95% CrI or Range*)	Specificity (95% CrI or Range*)
Fever	Adults	15 (2,082/1,796)	0.46 (0.29 to 0.64)	0.63 (0.47 to 0.77)
	Children	22 (3,952/3,845)	0.51 (0.41 to 0.61)	0.72 (0.66 to 0.77)
	Children <5 years	2 (196/77)	0.88 (0.83 to 0.93)	0.34 (0.29 to 0.39)
	Women of reproductive age	2 (37/36)	0.36 (0.20 to 0.53)	0.94 (0.89 to 1.00)
	Pregnant women	10 (309/166)	0.33 (0.14 to 0.59)	0.65 (0.37 to 0.86)
	Mixed	33 (8,766/5,386)	0.50 (0.39 to 0.61)	0.72 (0.62 to 0.80)
Guarding	Adults	5 (771/1,158)	0.67 (0.36 to 0.89)	0.69 (0.43 to 0.87)
	Children	8 (870/1,554)	0.64 (0.49 to 0.77)	0.69 (0.54 to 0.81)
	Women of reproductive age	1 (17/27)	0.76	0.85
	Pregnant women	4 (144/103)	0.63 (0.14 to 0.76)	0.55 (0.43 to 0.74)
	Mixed	18 (3,151/4,231)	0.63 (0.47 to 0.78)	0.69 (0.53 to 0.81)
Pain Migration	Adults	11 (1,831/864)	0.56 (0.45 to 0.67)	0.65 (0.50 to 0.78)
	Children	15 (2,049/3,535)	0.57 (0.39 to 0.73)	0.74 (0.66 to 0.81)
	Women of reproductive age	1 (17/27)	0.53	0.67
	Pregnant women	1 (42/14)	0.57	0.86
	Mixed	23 (4,475/6,156)	0.61 (0.49 to 0.71)	0.67 (0.56 to 0.76)
Tenderness	Children	2 (206/474)	0.63 (0.26 to 1.00)	0.57 (0.46 to 0.68)
	Children <5 years	1 (155/28)	0.98	0.25
	Women of reproductive age	1 (17/27)	1.00	0.04
	Mixed	10 (1,450/1,510)	0.99 (0.95 to 1.00)	0.30 (0.08 to 0.67)
Rebound Tenderness	Adults	11 (1,423/1,540)	0.67 (0.50 to 0.81)	0.70 (0.51 to 0.83)
	Children	11 (1,013/1,895)	0.60 (0.43 to 0.77)	0.73 (0.57 to 0.84)
	Children <5 years	1 (155/28)	0.85	0.86
	Women of reproductive age	1 (26/79)	0.42	0.65
	Pregnant women	5 (160/111)	0.71 (0.36 to 0.92)	0.58 (0.21 to 0.88)
	Mixed	30 (5,859/6,738)	0.74 (0.65 to 0.82)	0.60 (0.48 to 0.72)

\*We report sensitivity and specificity values as medians and report central 95% credible intervals (95% CrI) when  $\geq 5$  studies were available. We report medians and minimum-to-maximum values when  $< 5$  studies were available. When a single study was available, we report the estimate from that study.

## Test Performance of Laboratory Tests (in Isolation)

Table B presents key test performance results for selected laboratory tests. The performance of individual laboratory tests was also rather limited, but it was better than that of clinical symptoms and signs. There was substantial heterogeneity in sensitivity and specificity for most laboratory tests. Nevertheless, in most cases, summary ROC lines appeared to fit the data relatively well.

**Table B. Summary estimates of test performance of laboratory values for the diagnosis of acute appendicitis**

Laboratory Value	Population	N studies (N Affected/N Unaffected)	Sensitivity (95% CrI or Range*)	Specificity (95% CrI or Range*)
CRP	Adults	15 (1,541/983)	0.84 (0.73 to 0.92)	0.67 (0.50 to 0.81)
	Children	22 (2,226/1,635)	0.73 (0.66 to 0.80)	0.72 (0.61 to 0.81)
	Elderly	2 (213/72)	0.91 (0.91 to 0.92)	0.21 (0.17 to 0.25)
	Women of reproductive age	3 (169/133)	0.79 (0.44 to 0.97)	0.70 (0.33 to 0.93)
	Pregnant women	1 (31/8)	0.68	0.50
	Mixed	52 (8,742/5,903)	0.79 (0.74 to 0.83)	0.65 (0.57 to 0.72)
WBC	Adults	26 (4,070/2,452)	0.81 (0.74 to 0.87)	0.54 (0.42 to 0.64)
	Children	41 (6,595/4,473)	0.80 (0.73 to 0.85)	0.65 (0.56 to 0.73)
	Elderly	3 (287/82)	0.71 (0.69 to 0.77)	0.50 (0.38 to 0.70)
	Women of reproductive age	2 (49/18)	0.64 (0.60 to 0.69)	0.67 (0.67 to 0.67)
	Pregnant women	6 (197/82)	0.63 (0.21 to 0.92)	0.75 (0.38 to 0.95)
	Mixed	84 (19,074/10,883)	0.78 (0.75 to 0.82)	0.62 (0.58 to 0.66)
WBC + CRP	Adults	2 (194/68)	0.93 (0.86 to 1.00)	0.62 (0.37 to 0.86)
	Children	5 (566/132)	0.81 (0.42 to 0.96)	0.73 (0.54 to 0.85)
	Elderly	1 (77/8)	0.96	0.13
	Women of reproductive age	1 (29/9)	0.93	0.44
	Mixed	15 (4,145/1,734)	0.72 (0.42 to 0.91)	0.73 (0.54 to 0.88)

CRP = C-reactive protein; WBC = white blood cell count

\*We report sensitivity and specificity values as medians and report central 95% credible intervals (95% CrI) when  $\geq 5$  studies were available. We report medians and minimum-to-maximum values when  $< 5$  studies were available. When a single study was available, we report the estimate from that study.

## Test Performance of Multivariable Diagnostic Scores

Information on one or more multivariable diagnostic scores was reported in 127 studies. The authors usually proposed two types of cutpoints for these scores: a low value, below which patients might be safely discharged or observed (we refer to this cutpoint as the “low-risk cutoff”), and a high value, above which patients should be referred for treatment without additional investigation (we refer to this cutoff as the “high-risk cutoff”). The low- and high-risk cutoff values can be used to define three patient groups at different risk for appendicitis: low, intermediate, and high risk. If the diagnostic score has adequate classification performance and good calibration, the preferred test-and-treat strategy for each group will be different. When studies reported results at multiple cutpoints, we performed analyses at low-risk and high-risk cutpoints suggested by the original score developers or recommended in studies conducted after

the ones examined. For scores developed specifically for binary classification, we used a single cutpoint. Test performance results for commonly used scores are presented in Tables C and D.

The majority of multivariable diagnostic scores were developed prior to the widespread use of diagnostic imaging with CT and US. More recently developed scores were designed with the intention of identifying a low-risk group in which imaging can be omitted. Furthermore, multivariable models were often developed and evaluated in the same patient sample. It is likely that the lack of separation between the training and testing datasets led to optimistic estimates of test performance. Lack of external validation also limited our ability to assess the generalizability of many diagnostic scores.

**Table C. Summary estimates of test performance of Alvarado diagnostic score test (low-risk cutoff) for the diagnosis of acute appendicitis**

Test	Population	N Studies (N Affected/N Unaffected)	Sensitivity (95% CrI or Range*)	Specificity (95% CrI or Range*)
Alvarado	Adults	3 (407/264)	0.91 (0.89 to 0.93)	0.31 (0.24 to 0.78)
	Children	6 (674/898)	0.99 (0.92 to 1.00)	0.48 (0.24 to 0.74)
	Mixed	20 (3,986/4,073)	0.96 (0.92 to 0.98)	0.46 (0.34 to 0.58)
	Women of reproductive age	2 (89/50)	0.99 (0.98 to 1.00)	0.24 (0.22 to 0.25)
	Children <5 years	1 (17/10)	1.00	0.20

\*We report sensitivity and specificity values as medians and report central 95% credible intervals (95% CrI) when  $\geq 5$  studies were available. We report medians and minimum-to-maximum values when  $< 5$  studies were available. When a single study was available, we report the estimate from that study.

**Table D. Summary estimates of test performance of diagnostic score tests (high-risk cutoff) for the diagnosis of acute appendicitis**

Test	Population	N Studies (N Affected/ N Unaffected)	Sensitivity (95% CrI or Range*)	Specificity (95% CrI or Range*)
Alvarado	Adults	16 (2,354/1,212)	0.75 (0.59 to 0.87)	0.75 (0.57 to 0.87)
	Children	9 (855/1,163)	0.85 (0.75 to 0.93)	0.84 (0.61 to 0.96)
	Mixed	30 (4,475/4,337)	0.77 (0.69 to 0.84)	0.79 (0.74 to 0.84)
	Women of reproductive age	5 (202/177)	0.70 (0.35 to 0.92)	0.91 (0.65 to 0.99)
	Children <5 years	1 (17/10)	0.76	0.60
Alvarado Modified	Adults	4 (254/126)	0.68 (0.54 to 0.89)	0.60 (0.14 to 0.89)
	Children	5 (109/110)	0.89 (0.71 to 0.98)	0.80 (0.37 to 0.97)
	Elderly	1 (7/10)	0.86	0.80
	Mixed	6 (412/139)	0.82 (0.63 to 0.93)	0.62 (0.24 to 0.89)
	Women of reproductive age	4 (186/69)	0.60 (0.17 to 0.91)	0.50 (0.17 to 1.00)
PAS	Children	1 [108/18]	0.95	0.11

PAS = Pediatric Appendicitis Score

\*We report sensitivity and specificity values as medians and report central 95% credible intervals when  $\geq 5$  studies were available. We report medians and minimum-to-maximum values when  $< 5$  studies were available. When a single study was available, we report the estimate from that study.

## Test Performance of Imaging Tests

Table E presents key test performance results for selected imaging tests. Positive and negative LR<sub>s</sub> were generally higher for CT and MRI than for US, but all three tests had LR<sub>s</sub> that are clinically relevant ( $> 5$  and  $< 0.2$  for positive and negative LR<sub>s</sub>, respectively). US had substantially higher rates of nondiagnostic exams. The median percentage of nondiagnostic scans for CT was lower than 6% for all populations examined; the median proportion was substantially higher for US (ranging from 0% in women of reproductive age to 77.3% in pregnant women). However, the reporting of information on nondiagnostic scans was inconsistent across studies,

raising concerns about reporting bias. The full report presents the results of sensitivity analyses for the test performance of imaging tests under different assumptions about nondiagnostic scans. Heterogeneity in sensitivity and specificity was moderate or high for most tests with adequate data for assessment, yet in most cases summary ROC lines appeared to fit the data relatively well. CT had high sensitivity (summary estimates ranging from 0.95 to 1) and specificity (0.91 to 0.99) in all populations of interest for this report. MRI had high sensitivity (0.91 to 1) but appeared to have variable specificity (0.86 to 1), mainly because of the smaller number of available studies, and the findings are most applicable to pregnant women. In adult populations, US had lower sensitivity (0.83) and specificity (0.89) than CT and MRI, and produced more nondiagnostic scans. In children, the specificity of US was similar to that of CT (0.92 vs. 0.91), but CT had greater sensitivity (0.89 vs. 0.96); these results were based on a large number of studies (72 for US and 32 for CT). In the same patient population, MRI had a specificity of 0.99 and sensitivity of 1, but data were derived from only three studies and are therefore less reliable than those for other imaging tests. Among pregnant women, CT (5 studies), MRI (10 studies), and US (10 studies) had similar specificity (0.98, 0.98, and 0.95, respectively), but CT and MRI had higher sensitivity than US (0.95, 0.98, and 0.73, respectively).

**Table E. Summary estimates of test performance of diagnostic imaging for acute appendicitis**

Test	Population	N Studies (N Affected/N Unaffected)	Sensitivity (95% CrI or Range*)	Specificity (95% CrI or Range*)
CT	Adults	72 (7,833/14,469)	0.96 (0.95 to 0.97)	0.96 (0.93 to 0.97)
	Children	34 (3,581/3,122)	0.96 (0.94 to 0.98)	0.92 (0.85 to 0.96)
	Elderly	4 (144/582)	1.00 (0.94 to 1.00)	1.00 (0.43 to 1.00)
	Women of reproductive age	11 (596/652)	0.99 (0.96 to 1.00)	0.91 (0.75 to 0.97)
	Pregnant women	5 (26/84)	0.99 (0.96 to 1.00)	0.91 (0.75 to 0.97)
	Mixed	93 (9,341/10,357)	0.96 (0.95 to 0.97)	0.94 (0.91 to 0.95)
MRI	Adults	7 (512/467)	0.95 (0.88 to 0.98)	0.92 (0.87 to 0.95)
	Children	7 (359/665)	0.97 (0.87 to 1.00)	0.96 (0.84 to 0.99)

	Pregnant women	13 (188/198)	0.72 (0.45 to 0.92)	0.95 (0.84 to 0.99)
	Mixed	125 (11,902/14,314)	0.86 (0.83 to 0.89)	0.90 (0.87 to 0.92)

CT = computed tomography; MRI = magnetic resonance imaging; US = ultrasound

\*We report sensitivity and specificity values as medians and report central 95% credible intervals when  $\geq 5$  studies were available. We report medians and minimum-to-maximum values when  $< 5$  studies were available. When a single study was available, we report the estimate from that study.

## Test Performance of Diagnostic Laparoscopy

Fifty-five studies published between 1974 and 2014 reported information on the test performance of diagnostic laparoscopy. The reporting of methods and outcomes in these studies was less complete than that of studies of other tests. When possible to discern such information

from the reported data, patients undergoing diagnostic laparoscopy often presented atypically and had already been examined with a number of other diagnostic modalities. In addition, studies of laparoscopy did not fully report information on the final diagnosis of patients for whom the procedure did not reveal an inflamed appendix. Studies often did not report operational definitions for the absence of any pathology and had heterogeneous management policies for such cases. These features of the studies can influence the estimates of test performance; for this reason, we did not perform any quantitative synthesis for the test performance of diagnostic laparoscopy. It is important to note that patients included in studies of diagnostic laparoscopy are likely to be different from patients included in studies of noninvasive tests, even if the selection criteria are not clearly presented. They may, for example, have more severe symptoms or have atypical findings on other tests. Thus, indirect comparisons of diagnostic laparoscopy with noninvasive tests are not meaningful.

### **Sensitivity and Specificity**

For the 54 studies for which they could be calculated, the median sensitivity and specificity were 100 and 89 percent, respectively. However, there was a wide range, with sensitivity ranging from 37 to 100 percent (25<sup>th</sup> percentile, 95%; 75<sup>th</sup> percentile, 100%) and specificity ranging from 0 to 100 percent (25<sup>th</sup> percentile, 73%; 75<sup>th</sup> percentile, 100%). This variability likely reflects the heterogeneous populations evaluated in these studies. In the 16 studies that reported on women of reproductive age, the median sensitivity was 100 percent (25<sup>th</sup> percentile, 100%; 75<sup>th</sup> percentile, 100%), and the median specificity was 89 percent (25<sup>th</sup> percentile, 79%; 75<sup>th</sup> percentile, 100%).

### **Tests Positive for Other Pathology**

Forty-one studies reported some information on other pathology diagnosed at laparoscopy. The median proportion of patients identified with nonappendiceal pathology was 22 percent (25<sup>th</sup> percentile, 11.5%; 75<sup>th</sup> percentile, 34%). Only six small studies reported that other pathology was found when appendicitis was also present. The median was 5 percent (25<sup>th</sup> percentile, 2%; 75<sup>th</sup> percentile, 13%). In studies of women of reproductive age, the median proportion of patients identified with nonappendiceal pathology was 23 percent (25<sup>th</sup> percentile, 18%; 75<sup>th</sup> percentile, 26%); no nonappendiceal pathologies were found in patients who had appendicitis.

### **Other**

Information on other test performance outcomes of diagnostic laparoscopy—for example, the proportion of cases in which the appendix could not be visualized and the proportion of cases in which no cause of pain was identified (i.e., nonproductive abdominal explorations)—is presented in the full report.

### **Modifiers of Test Performance**

The vast majority of studies did not report adequate data to assess factors that may affect test performance; for this reason we relied on comparisons across studies via meta-regression analyses to identify such factors. Overall, no distinct pattern emerged to establish a particular factor as a modifier of test performance. For all clinically relevant factors examined, credible intervals were wide, indicating substantial uncertainty regarding the relative performance of tests over levels of the modifiers. Details on the impact of patient- and test-related characteristics on the test performance of various tests in specific subpopulations are presented in the full report.

## **Comparative Assessments of Test Performance**

Our assessment of comparative test performance relied on randomized and nonrandomized direct (i.e., within-study) comparisons of tests. Overall, on the basis of items from the Cochrane risk-of-bias tool, RCTs were deemed to be at moderate risk of bias. NRCSs were at high risk of bias because they either did not make any attempt to address differences among groups receiving different test strategies or failed to consider at least some important factors (e.g., age, sex, or duration and severity of symptoms).

### **Randomized Comparisons of Alternative Tests**

Although 36 RCTs reported information on comparative test performance, each possible comparison was examined by only one or two small trials, and these trials did not report information on the same outcomes. Therefore, it was not possible to draw strong conclusions about the comparative performance of different tests.

### **Nonrandomized Comparisons of Alternative Tests**

#### **Nonrandomized Comparisons of Diagnostic Scores**

Eight studies reported direct comparisons among alternative diagnostic scores for appendicitis. Three studies included only children, one included women of reproductive age, and four included mixed populations. Across all eight studies, differences in test performance between scores were small; this was particularly true for the comparison of the Alvarado score and Pediatric Appendicitis Scores applied to children with suspected acute appendicitis. The one exception was a study that compared a multivariable diagnostic score based on clinical symptoms and signs versus a score combining the same clinical variables with the addition of US: incorporation of imaging information improved test performance substantially with respect to both sensitivity and specificity.

#### **Nonrandomized Comparisons of CT and US**

Fifty-three studies reported results in cohorts using both CT and US as index tests, potentially permitting direct nonrandomized comparisons of these modalities. Ten studies investigated CT as a replacement for US, 13 investigated US as a triage test for CT, and 30 studies were unclear about the actual role of testing that was being evaluated (often using convenience samples of patients selected using criteria that were poorly reported). Nine of the studies had a paired design and 44 had a parallel-group design. In general, CT had better test performance than US when used as a replacement test or when the role of testing being evaluated was unclear. In the triage context, CT had high test performance (diagnostic odds ratios higher than 10 and often higher than 100) in patient populations selected on the basis of US results (typically, patients with nondiagnostic US findings or negative US findings in the presence of symptoms suggestive of appendicitis).

#### **Nonrandomized Comparisons of MRI and US**

Eight studies reported results in cohorts using both MRI and US as index tests. Four studies investigated MRI as a replacement for US, one investigated US as a triage test for MRI, and three studies were unclear about the actual role of testing that was being evaluated (tending to use convenience samples of patients selected for a specific test using criteria that were poorly reported). Four of the studies had a paired design and four had a parallel-group design. MRI,

when used as a replacement test for US, had greater test performance; however, the available studies are few and, when combined, produce rather imprecise results.

## **Key Question 2: What is the comparative effectiveness of alternative diagnostic tests, alone or in combination, for patients with RLQ pain and suspected acute appendicitis?**

Of 925 included studies, 54 reported information on comparative effectiveness outcomes related to diagnostic tests (36 RCTs and 18 NRCSs). Many of the included RCTs were small and may have produced unstable estimates of event rates and treatment effects. Furthermore, selection criteria differed substantially among trials, rendering cross-study comparisons uninformative.

## **Key Question 3: What are the harms of diagnostic tests per se, and what are the treatment-related harms of test-directed treatment for tests used to diagnose RLQ pain and suspected acute appendicitis?**

Of 925 included studies, only 83 mentioned harms related to diagnostic tests: 17 RCTs, 13 NRCSs, and 53 diagnostic cohort studies. Eight studies (3 RCTs and 5 diagnostic cohort studies) reported an absence of adverse events for all tests except diagnostic laparoscopy. The fact that so few studies reported harms raises concerns about selective outcome reporting.

### **Contrast-Related Adverse Events**

Eight studies (3 RCTs and 5 diagnostic cohort studies) reported on adverse events related to contrast administration. Of these, three reported that the contrast was well tolerated. The others reported a combination of nonfatal adverse events.

### **Exposure to Ionizing Radiation**

No studies reported direct evidence on the effect of ionizing radiation on patient-relevant outcomes. Twelve studies (3 RCTs, 4 NRCSs, and 5 diagnostic cohort studies) reported radiation doses for CT, and three of these discussed strategies to reduce CT-related radiation exposure in a population, but they did not link this information with clinical outcomes.

### **Maternal/Fetal Adverse Events**

Six studies (3 studies of US, 3 of MRI, and 2 of multiple clinical and lab tests, some studies evaluating more than 1 test) reported information on maternal outcomes. One study of MRI reported that 17 patients without appendicitis progressed to uneventful labor and delivery. A second study of MRI reported that not using oral contrast sped up the imaging process. The remaining four studies reported that there was no maternal mortality.

Seven studies (5 studies of US, 2 of MRI, 1 of CT, and 1 of clinical symptoms and signs, some studies evaluating more than 1 test) reported information on fetal outcomes. One study of US reported that 18 of 22 patients had a normal-term delivery; there were two spontaneous abortions (in patients with no clinical or sonographic evidence of acute appendicitis) and two elective abortions. The second study examined US and clinical and laboratory tests, and found that all 20 women delivered healthy infants. The third study gave fetal outcomes for only 2 of the 45 participants who underwent US for the diagnosis of appendicitis. One was a spontaneous abortion in a woman with surgically confirmed acute appendicitis without perforation, and the

other was a premature delivery in a patient with no evidence of appendicitis at followup through delivery. The fourth study reported a total of nine adverse fetal outcomes (5/31 who had MRI and 4/44 in the US or clinical group); none were in the perioperative period. The fifth study reported outcomes for US, MRI, and CT. In the US group, one patient, who had an open appendectomy in the first trimester, developed severe preeclampsia and had a premature delivery at 33 weeks. (This patient also had a diagnostic CT.) There was one fetal death after a negative open appendectomy, but neither the fetal death nor the early delivery was related directly to the appendectomy, and one patient with perforated appendicitis had abruptio placentae and vaginal hemorrhage. Only one patient had MRI, and she delivered a healthy baby at term. Of 13 patients who had a diagnostic CT, 9 delivered healthy infants; 1, who had an open appendectomy in the first trimester, developed severe preeclampsia and had a premature delivery at 33 weeks (previously mentioned); and 3 were lost to followup. The sixth study reported fetal outcomes for 55 of 80 patients who had CT. Fifty-one had a live infant at or near term, one had a premature delivery of a live 30-week infant 3 days after CT-diagnosed gastric cancer, two had spontaneous vaginal delivery of a nonviable fetus (1 at 18 weeks with sepsis after normal CT and normal laparotomy, and 1 at 22 weeks with chorioamnionitis, 5 days after normal CT). There was one fetal death at 26 weeks (4 weeks after a CT examination with normal findings). The seventh study reported that in a group evaluated using symptoms and signs, there were seven therapeutic abortions and two perioperative spontaneous abortions (first trimester), and four women without appendicitis had severe perinatal morbidity or mortality.

## **Surgical Complications in Studies of Diagnostic Laparoscopy**

Thirty-four studies of diagnostic laparoscopy mentioned surgery-related harms. Eight RCTs (469 patients) and 8 NRCSs (4,084 patients) described complications related to laparoscopy compared with open appendectomy; 25 diagnostic cohort studies (5,553 patients) reported on complications of diagnostic laparoscopy. In general, the rates of specific complications were low (generally less than 10% and in most cases less than 2%). Few studies attributed specific adverse events to diagnostic laparoscopy (as opposed to additional surgical intervention). Nine studies, including five RCTs, reported that there were no complications related to the diagnostic laparoscopic procedure.

## **Discussion**

### **Key Findings and Strength-of-Evidence Assessment**

The literature on the test performance of various clinical symptoms and signs, laboratory and imaging tests, and diagnostic scores is vast but consists almost exclusively of studies assessing the test performance of individual tests. Information on test performance of multiple tests applied jointly and conditional test performance (i.e., test performance among patients already examined with other tests) was limited. The few studies that provided information on more than one index test were typically not designed with the goal of providing comparative information, and cross-study comparisons cannot provide reliable evidence on relative performance. Studies meeting our selection criteria provided limited information on the test performance or comparative effectiveness of diagnostic pathways (i.e., well-defined sequences of diagnostic and treatment steps). We assessed the strength of evidence for key outcomes selected on the basis of our reading of the literature and discussions with Key Informants and Technical Experts. Our

assessment integrates subjective judgments on risk of bias, consistency of findings, directness of the available information, and precision of estimates.

## Test Performance

Clinical symptoms and signs used in isolation, including classical signs of peritoneal irritation, fever, and various assessments of abdominal pain, appeared to have limited test performance for all the populations of interest to this report. Among laboratory tests, white blood cell count, C-reactive protein, and tests derived from combinations of measurements on the complete blood count and differential had test performance that was generally higher than that of clinical symptoms and signs (especially with respect to sensitivity using a low-risk threshold) but still rather limited (e.g., in terms of summary LRs). These observations were relatively stable across the patient populations examined. Because studies did not allow an examination of the performance of multiple tests applied jointly and because conditional test performance was not reported uniformly across studies, the clinical implications of the relatively limited test performance of many nonimaging tests is not clear. Furthermore, symptoms and signs are variable in a patient (over the course of disease) and among patients, and it is hard to assess their clinical usefulness based on test performance. Importantly, the clinical examination forms the basis of the investigation of acute abdominal pain and suspected acute appendicitis and, even if poorly reported, all studies of imaging tests use some form of clinical examination (e.g., for patient selection). Multivariable diagnostic scores appeared to have test performance that was superior to the individual clinical signs, symptoms, or laboratory tests they included but still rather limited (e.g., in terms of summary LRs). Of note, the majority of studies assessed scores that had been developed before the widespread availability of CT and US imaging, suggesting that their results may be less applicable to current clinical practice.

Among imaging tests, CT and MRI had high sensitivity and specificity, resulting in clinically relevant summary LRs. CT has been investigated in a large number of diagnostic cohort studies, leading to precise estimates of test performance in all populations of interest for this report. In contrast, MRI has been investigated in a relatively small number of studies, mainly focused on pregnant women; therefore, the results may not be applicable to other populations. US has been investigated in a large number of studies and results were somewhat heterogeneous, suggesting that the average estimate of test performance may not apply to all populations for which US is considered. Possible explanations for this heterogeneity are the operator dependence of the test performance of US and the fact that studies were conducted in different settings. Despite the heterogeneity, the data suggest that US had lower overall test performance than CT and MRI, and resulted in a substantially greater proportion of nondiagnostic examinations. Diagnostic laparoscopy appeared to have good test performance, but studies were poorly reported and differed in their policies regarding removal of the appendix when no pathology was macroscopically visible, which may bias test performance results. Furthermore, patients included in studies of diagnostic laparoscopy are likely to be very different from patients included in studies of noninvasive tests. Therefore, our results for the test performance of laparoscopy should not be compared with the other diagnostic tests reviewed in this report. Table F summarizes our findings regarding the strength of evidence for the diagnostic performance of selected tests. When interpreting these results, readers should remember that test performance is not directly related to clinical outcomes, and high sensitivity and specificity do not necessarily imply better patient-relevant outcomes.

**Table F. Assessment of the strength of evidence for test performance of individual tests**

Test or Score	Strength of Evidence	Test Sensitivity in Key Subgroups—Subgroup (N Studies): Sensitivity (95% CrI)	Test Specificity in Key Subgroups—Subgroup (N Studies): Specificity (95% CrI)
WBC count	Moderate	Adults (26): 0.81 (0.74 to 0.87) Children (41): 0.80 (0.73 to 0.85) Elderly (3): 0.71 (0.69 to 0.77) Women of reproductive age (2): 0.64 (0.60 to 0.69) Pregnant women (6): 0.63 (0.21 to 0.92)	Adults (26): 0.54 (0.42 to 0.64) Children (41): 0.65 (0.56 to 0.73) Elderly (3): 0.50 (0.38 to 0.70) Women of reproductive age (2): 0.67 (0.67 to 0.67) Pregnant women (6): 0.75 (0.38 to 0.95)
CRP	Low	Adults (15): 0.84 (0.73 to 0.92) Children (22): 0.73 (0.66 to 0.80) Elderly (2): 0.91 (0.91 to 0.92) Women of reproductive age (3): 0.79 (0.44 to 0.97) Pregnant women (1): 0.68	Adults (15): 0.67 (0.50 to 0.81) Children (22): 0.72 (0.61 to 0.81) Elderly (2): 0.91 (0.91 to 0.92) Women of reproductive age (3): 0.79 (0.44 to 0.97) Pregnant women (1): 0.68

Laparoscopy	Moderate	Please see the Results section in the main report for a full description of results related to diagnostic laparoscopy	—

CBC = complete blood count; CrI = credible interval; CRP = C-reactive protein; CT = computed tomography; MRI = magnetic resonance imaging; PAS = Pediatric Appendicitis Score; US = ultrasound; WBC = white blood cell count

Comparisons among tests with respect to test performance relied on a small number of RCTs with moderate risk of bias, a relatively small number of direct comparisons among index tests in diagnostic cohort studies that were not designed to obtain comparative information, and indirect comparisons across single index test studies enrolling diverse populations in heterogeneous clinical settings. There was moderate-strength evidence that CT has superior overall test

performance compared with US and produces fewer nondiagnostic results. Similarly, MRI appeared to have better test performance than US, but the strength of evidence was deemed low. The strength of evidence on comparisons among other imaging tests and among multivariable diagnostic scores was deemed insufficient. The evidence regarding the effect of patient- and test-related characteristics on test performance was also deemed insufficient. There were indications that aspects of study design characteristics affect test performance, but the effects are often unpredictable in direction and do not have direct clinical relevance.

## **Patient-Relevant Outcomes**

We based our assessment of the comparative effectiveness of alternative tests on randomized studies (with the exception of outcomes among pregnant women), because indirect (across studies) comparisons of outcomes other than test performance are susceptible to bias resulting from differences among the populations included. We found a few RCTs with moderate risk of bias that provided information on the comparative effectiveness of alternative testing strategies. These studies assessed various comparisons across different modalities (or different versions of the same modality) and therefore did not provide definitive evidence for any of the possible pairwise contrasts they evaluated.

## **Adverse Events of Testing**

Information on harms was often incomplete and poorly reported. Only a minority of the included studies provided information on test-related harms, raising concerns about selective outcome and analysis reporting. The majority of the studies providing information on adverse events did not report the definitions or ascertainment methods they used. Importantly, no information was available from studies meeting our selection criteria regarding the effects of ionizing radiation. This is particularly important, as there is substantial variation in the levels of radiation delivered with newer multiphase CT scans performed for evaluation of appendicitis. Information was particularly limited on fetal and maternal outcomes of various diagnostic modalities applied during pregnancy for the investigation of acute appendicitis. Overall, we rated the strength of evidence on the harms of tests for acute appendicitis to be insufficient, primarily because of concerns about outcome reporting bias and the sparseness of available evidence.

## **Limitations of the Evidence Base**

The evidence base regarding the diagnosis of acute appendicitis is limited in the following ways:

- Studies reporting information on test performance outcomes were at moderate to high risk of bias. Differential verification (the use of different reference-standard tests depending on the results of the index test) and partial verification (the failure to apply the reference standard to all of the included patients) were common, particularly in studies that were not surgical series (generally, studies with a lower prevalence of appendicitis). Studies with complete and nondifferential verification tended to be surgical cohorts reporting exclusively on patients undergoing appendectomy and so are not representative of all patients presenting with acute RLQ pain. In addition, poor reporting of information on study design hampered our risk-of-bias assessment.
- Studies provided limited information to assess the impact of various factors related to patients, technical implementation, operators, or systems on the performance of the tests of interest.

- Information on the comparative effectiveness of alternative testing strategies (e.g., sequential use of tests as part of a diagnostic algorithm) with respect to test performance, patient-relevant outcomes, and resource use was limited. Direct (within study) comparisons of test performance and the impact of testing strategies on clinical outcomes were scarce. Studies have not compared diagnostic algorithms (e.g., combinations of tests applied in sequence, such that the results of earlier tests determine the choice of subsequent tests). When two or more index tests were evaluated in the same study, the role of testing that was being examined (add-on, replacement, triage) was often unclear.
- In studies of diagnostic scores, multivariable models were often developed and evaluated in the same patient sample. The lack of separation between the training and testing datasets (or any attempt at internal validation of the model) generally leads to optimistic (too high) estimates of test performance. The lack of external validation (replication) also limited our ability to assess the generalizability of many diagnostic scores.
- Few RCTs compared alternative test strategies with respect to patient-relevant outcomes. The few trials reporting patient-relevant outcomes were fragmented across heterogeneous comparisons of alternative testing strategies. The trials often used suboptimal methods for randomized sequence generation, allocation concealment, and blinding, or they provided information that was too limited to assess these aspects of study design. Many had sample sizes that were too small to reliably detect small or moderate differences between the strategies being compared.
- In contrast to the RCTs, NRCSs of alternative testing strategies attained large sample sizes but often reported unadjusted analyses (or analyses adjusted for only a small number of potential confounders) that do not allow strong conclusions about the comparative effectiveness of alternative test strategies to be drawn.

## **Strengths and Limitations of This Review**

Previous reviews on this topic have focused on special patient populations, have almost exclusively focused on test performance outcomes, have not assessed harms systematically, or have focused on a very limited spectrum of study designs. Our work provides a comprehensive up-to-date summary of the evidence on the diagnosis of RLQ pain and suspected acute appendicitis. For many of the examined tests and patient populations, this review is the first to be conducted. For some important modalities that have been investigated to some extent in previous meta-analyses (e.g., CT, MRI, US, and multivariable diagnostic scores), our work includes a much larger number of studies (and a greater total number of patients) than previous reviews. This allows us to provide accurate estimates of test performance in different patient populations that can be used to inform clinical decisions (especially if used as inputs in decision and simulation models) and to identify evidence gaps to inform the planning of future research.

Nonetheless, several limitations, which to a large extent reflect the limitations of the underlying evidence base, must be considered when interpreting our results.

- The evidence base has a number of limitations, detailed in the preceding section: quality was often poor, patient-relevant outcomes and harms were incompletely and inconsistently reported, and information on study- or population-level characteristics that could modify test performance and patient-relevant outcomes was also incomplete.
- We assumed that pathological diagnosis and clinical followup have negligible error (i.e., that they represent a “gold” standard). It is unlikely that this assumption is exactly true. Consequently, it is likely that estimates of test performance are biased, and the direction

of this bias is hard to predict, particularly at the meta-analysis level. However, we believe that the error rate of these reference standards is low enough that its influence on our estimates is relatively small.

- Finally, we did not address contextual factors (e.g., availability of equipment, trained readers) that are important determinants of the adoption of specific diagnostic strategies in particular settings.

## **Applicability of Review Findings**

In general, the existing evidence on alternative diagnostic tests for the diagnosis of acute RLQ pain and suspected acute appendicitis appears to be applicable to clinical practice in the United States. The included studies enrolled patients representative of the age and sex distribution of patients seeking care for RLQ abdominal pain in the United States, and evidence on test performance was available for all commonly used modalities. Information on adults and children was often separately reported, allowing the assessment of test performance in these patient subgroups. However, information was more limited for patients at the extremes of age (i.e., children younger than 5 years or the elderly), pregnant women, and women of reproductive age; in some cases, decisions for these will have to rely on extrapolation of results from population subgroups with more available information, and thus applicability assessments are not possible. Approximately one-third of the studies in this review were conducted in the United States, and the vast majority were carried out either in the United States or in industrialized European or Asian countries. Care settings varied across studies, including academic and nonacademic centers, and patient populations included those sampled at emergency departments, in surgical cohorts, or from mixed populations.

Assessing the applicability of studies on clinical symptoms and signs was challenging: the pathophysiologic rationale for many of these tests is well established, but many of the relevant studies were conducted before the widespread availability of imaging modalities, and thus their findings may reflect test performance in a population with more advanced disease or populations selected for a high probability of appendicitis (e.g., surgical cohorts). Studies of laboratory and imaging tests evaluated “stable” technologies (e.g., white blood cell count) or were conducted in recent years; for example, many studies of C-reactive protein, CT, and US were conducted from 2005 onward. In meta-regression analyses comparing test performance in the last decade against earlier years, there was no evidence that the performance of laboratory or imaging tests has changed significantly over time; however, the indirect nature of metaregression comparisons and the low precision of metaregression estimates limit the strength of these results. In contrast, the applicability of the evidence on most multivariable diagnostic scores may be somewhat limited because most were developed before the era of widespread availability of imaging. The lack of external validation for most diagnostic scores also limits the applicability of these results. The findings of studies on diagnostic laparoscopy may also be less applicable because many of the studies were conducted before the widespread availability of diagnostic imaging.

## **Future Research Needs**

### **Studies of Diagnostic Test Performance**

- Cohort studies of test performance would provide useful information, particularly for diagnostic tests that have not been studied adequately (e.g., MRI in all relevant patient populations) and to compare the performance of tests for which comparative information

is limited (e.g., direct comparisons of CT vs. US; comparisons between CT with contrast administered via alternative routes).

- Such diagnostic cohort studies (and comparative studies in particular) are also needed to evaluate the test performance of combinations of tests and testing strategies by estimating conditional test performance and by developing and validating multivariable diagnostic tools internally and in independent datasets. For example, they could examine the use of US as a triage test for CT or MRI, or the use of multivariable diagnostic scores to select patients who can be monitored without immediate imaging or treatment (e.g., low-risk patients who can be managed with wait-and-see strategies), those who need imaging, and those who need the initiation of treatment without imaging. They can also provide information to determine how patient- and test-related factors affect performance (i.e., to examine whether test performance depends on easily identifiable patient characteristics).
- Research is needed on the natural history of acute appendicitis, specifically on whether (and how often) cases of appendicitis resolve on their own and the rate of recurrence among such cases. Studies of natural history (e.g., among patients deemed to be appropriate candidates for medical management or wait-and-see strategies) are necessary for evaluating the impact of tests in decision and simulation modeling studies (discussed later) and also to inform the design of studies of alternative test-and-treatment strategies, including studies of the sequencing of multiple tests and the timing of examinations. Of note, the test performance of diagnostic tests may vary during different timepoints in the development of acute appendicitis; for instance, laboratory tests may be highly sensitive for cases associated with more severe inflammation.
- Paired test study designs, in which all index tests are applied to all enrolled patients (so that each patient has results from every test of interest), are generally more efficient than parallel-arm designs and should be considered when planning future studies.<sup>65</sup>
- Cohort studies assessing the performance of tests that have been evaluated extensively (e.g., CT and US) are most needed for specific patient populations (e.g., pregnant women, young children, and the elderly); for other tests (e.g., MRI) further research is needed in all patient populations. Comparative studies are needed for all tests and all populations. Ideally, future studies of test performance will be large (powered to achieve adequate precision), prospectively designed, multicenter investigations enrolling patients representative of those seen in clinical practice. Studies should prespecify the criteria for a positive test, use standardized diagnostic criteria for the diagnosis of appendicitis, use followup for an adequate period of time (1–2 weeks) for patients who do not undergo surgery, and have as complete followup as possible. Studies that evaluate two or more index tests should provide a detailed description of the role of testing they are evaluating (triage, add-on, replacement) and report data in enough detail to allow statistical analyses appropriate for that evaluation.<sup>66</sup>
- Multivariable diagnostic scores provide an appealing way to combine information from multiple clinical symptoms and signs, laboratory tests, and possibly US. Multivariable scores may be particularly useful in identifying patients who are at low risk for appendicitis and who may be candidates for wait-and-see strategies or less aggressive imaging strategies. Cohort studies for the development and validation of such scores should use state-of-the science methods for model development and internal and external validation.

- Future research needs to be better reported and studies should adhere to established reporting guidelines (e.g., STAndards for the Reporting of Diagnostic accuracy studies; [www.stard-statement.org/](http://www.stard-statement.org/)).

## **Studies of Patient-Relevant Outcomes and Resource Use**

- Cohort studies of diagnostic test strategies can also be used to study the impact of tests on patient-relevant and resource use outcomes. For tests with well-understood performance characteristics, such studies may use randomized designs. In many cases, however, randomized comparisons of alternative test strategies are unlikely to be fruitful because existing studies indicate that many of the competing tests have sensitivities and specificities that are fairly similar and close to 1.<sup>67</sup> Under these conditions, RCTs comparing alternative test strategies would need to enroll very large numbers of participants to allow reliable comparisons. If randomized studies are deemed necessary, consideration should be given to paired randomized designs because they are more efficient than parallel-arm trials.
- Large-scale observational prospective studies could be used to evaluate the effectiveness of alternative test strategies with respect to short- and long-term patient-relevant outcomes and to explore factors that may modify the effect of tests on these outcomes. Such studies would need to collect detailed information on baseline factors that may be associated with the choice of test strategy and the outcomes of interest in order to attempt to address confounding bias. Comparisons across methods should be performed only among patients who would be candidates for assessment with all methods being compared.
- Decision and simulation modeling can be used to determine whether randomized or nonrandomized cohort studies assessing patient-relevant outcomes and resource use are necessary and to guide their design. Models can also be used to synthesize evidence on test performance, impact of tests on clinical decisions, treatment effectiveness, resource use (and, when relevant, economic costs), and patient preferences to guide clinical decisionmaking. We think that the results of the current review provide a solid basis for conducting such modeling studies.

## **Studies of Test-Related Adverse Events**

- Future studies should report complete information on test-related adverse events, using prespecified criteria and careful ascertainment methods.
- Mathematical modeling studies can be used to combine data on the effective radiation dose received during alternative CT-based approaches with external information on long-term radiation effects.<sup>67</sup>

## **Conclusions**

The literature on the test performance of clinical symptoms and signs, laboratory and imaging tests, and multivariable diagnostic scores for the diagnosis of acute appendicitis is large, but it consists almost exclusively of studies at moderate risk of bias, primarily because of differential and incomplete verification. The few studies that assess multiple tests are typically not designed with the goal of providing comparative information. Thus, the available evidence supports fairly strong conclusions about the performance of individual tests, but it is largely insufficient to support conclusions about comparative effectiveness, especially with respect to

clinical outcomes. Clinical symptoms and signs and laboratory tests have relatively limited test performance when used in isolation. Their combination in multivariable scores is promising, but the best studied scores were developed before the widespread use of imaging modalities, and more recently developed scores have not yet been studied adequately. All three major imaging modalities have adequate test performance. Evidence on CT is mature for most patient populations of interest. In contrast, MRI has been investigated in fewer studies, many of which focus on its use for pregnant women. US produces nondiagnostic scans more often than CT or MRI, and when a diagnosis is possible, its performance appears to be somewhat worse than CT and MRI. Beyond test performance, information on patient-relevant outcomes and resource use is very limited. Information on test-related harms (e.g., adverse events due to radiation) is provided by only a minority of studies and is poorly reported. More research, much of which could be accomplished through nonrandomized studies, is needed to establish the performance in understudied patient populations (very young children, women of reproductive age, the elderly) and modalities (e.g., MRI, multivariable scores); compare competing tests; identify factors that affect performance; and evaluate the impact of testing strategies on patient-relevant outcomes, resource use, and harms. Perhaps most importantly, given the large volume of accumulated evidence on the performance of various tests, decision and simulation modeling (e.g., decision analysis, simulation modeling of the impact of radiation on long-term outcomes) should be used to guide decisionmaking and to inform the design of future studies.

# Background

## Nature and Burden of the Condition

Abdominal pain is a common presenting complaint for patients seeking care at emergency departments, with approximately 3.4 million expected cases per year in the United States.<sup>1</sup> Appendicitis is a frequent cause of abdominal pain, caused by acute inflammation of the appendix, and occurs in approximately 8 to 10 percent of the population (over a lifetime).<sup>2,3</sup> Appendicitis has its highest incidence between the ages of 10 and 30 years. The ratio of incidence in men and women is 3:2 through the mid-20s and then equalizes after age 30. Appendicitis is the most common abdominal surgical emergency, with over 250,000 appendectomies performed annually in the U.S. The risk of acute appendicitis in pregnant women is similar to that of the general population, making appendicitis the most common non-obstetric emergency during pregnancy.<sup>4-7</sup> Untreated, appendicitis can lead to perforation of the appendix, which typically occurs within 24 to 36 hours of the onset of symptoms. Perforation of the appendix can cause intra-abdominal infection, sepsis, intraperitoneal abscesses, and rarely death.<sup>4</sup> In order to avoid the sequelae of perforated appendicitis, a low percentage of “negative” appendectomies (i.e., removing a normal, non-inflamed appendix in patients mistakenly diagnosed with appendicitis) is generally accepted from a surgical standpoint.

## Diagnosis of Suspected Acute Appendicitis

Guidelines suggest that when a diagnosis of acute appendicitis can be made on clinical grounds surgical consultation should be sought without delay for additional diagnostic testing.<sup>8</sup> Clinical symptoms and signs suggestive of appendicitis include a history of central abdominal pain migrating to the right lower quadrant (RLQ), anorexia, fever, and nausea/vomiting. On examination, RLQ tenderness, along with “classical” signs of peritoneal irritation (e.g., rebound tenderness, guarding, rigidity, referred pain), may be present. Other signs (e.g., the psoas or obturator signs) may help the clinician localize the inflamed appendix.<sup>9-11</sup> The performance of clinical symptoms and signs for identifying acute appendicitis seems to be variable across studies, many patients present atypically, and few clinical findings appear to have adequate sensitivity and specificity when used in isolation.<sup>10,11</sup>

For patients with right lower quadrant (RLQ) pain, when the diagnosis cannot be made on clinical grounds alone, laboratory or imaging tests are often used to attempt to establish a diagnosis and guide treatment. Laboratory evaluations potentially useful for the diagnosis of appendicitis include white blood cell count, granulocyte count, the proportion of polymorphonuclear blood cells, and C-reactive protein concentration.<sup>10-12</sup> Imaging tests, such as ultrasound (US), computed tomography (CT) with and without contrast, and magnetic resonance imaging (MRI), are also used extensively for the diagnosis of appendicitis.<sup>13-19</sup> Imaging tests can be used alone or in combination. For example, US is sometimes used as a triage test to separate patients in whom sonography alone is adequate to establish a diagnosis from those who require further imaging with CT.<sup>8</sup> Different factors may affect the performance of alternative tests and their impact on clinical outcomes. For example, US examination is considered to be operator dependent<sup>20</sup> and is technically challenging in obese patients or women in late pregnancy. CT scanning can be performed with or without the use of contrast agents, and contrast can be administered orally, rectally, intravenously, or via combinations of these routes.<sup>8</sup> It has been suggested that low body mass index (BMI), a marker for lack of sufficient mesenteric fat (which

helps visualize periappendiceal fat stranding, a radiological sign of appendicitis), may affect the relative test performance of CT performed with or without contrast (contrast being more useful in individuals with low BMI and children).<sup>8</sup>

Clinical symptoms and signs, along with the results of laboratory or imaging tests, can be combined into multivariable diagnostic scores (sometimes referred to as “clinical prediction rules”), multivariable that synthesize the findings of different investigations to determine the most likely diagnosis.<sup>21</sup> In adults, the most commonly used multivariable score for appendicitis is the Alvarado score,<sup>22</sup> which separates patients into 3 groups of increasing probability of appendicitis (the score is based on 8 items: pain migration, anorexia, nausea, tenderness in RLQ, rebound pain, elevated temperature, leukocytosis, and shift of white blood cell count to the left).<sup>23</sup> Although the Alvarado score is also used in pediatric populations,<sup>24,25</sup> the Pediatric Appendicitis Score has been developed and validated for use in children.<sup>26</sup> It is based on 9 items (migration of pain, anorexia, nausea/vomiting, fever, cough/percussion tenderness, hopping tenderness, RLQ tenderness, leukocytosis, polymorphonuclear neutrophilia) and classifies children into two groups (high vs. low probability of appendicitis).<sup>26</sup>

Diagnostic laparoscopy is also used for the evaluation of patients with RLQ pain and suspected acute appendicitis, primarily when a diagnosis cannot be established via other means. Although diagnostic laparoscopy is generally considered safe, studies have reported variable rates of morbidity and mortality from the procedure.<sup>27</sup>

In general the diagnostic tests discussed in this section are widely available in the U.S. Clinical symptoms and signs can be evaluated relatively easily and inexpensively. Evidence from the National Hospital Ambulatory Medical Care Survey suggested that CT and complete blood counts are obtained in the majority of patients presenting to the emergency department with abdominal pain. The survey also showed that over time (between 1992 and 2006) the use of CT for both adults and children has been increasing. Over the same period, the use of the complete blood count has increased in adults but decreased in children.<sup>28,29</sup> Various other sources suggest that the use of US and MRI is increasing in populations where exposure to ionizing radiation is a particular concern (e.g., children and pregnant women).<sup>30-36</sup>

## **Importance of Accurate Diagnosis and Impact on Outcomes**

As with all diagnostic tests, the modalities used in the diagnostic investigation of patients with RLQ pain/suspected appendicitis affect clinical outcomes indirectly, through their impact on clinicians’ diagnostic thinking and decisionmaking.<sup>37</sup> More accurate and timely diagnosis of appendicitis can minimize the time to the indicated intervention (e.g., surgery), thus reducing the time patients are in pain and improving clinical outcomes (e.g., reducing the rate of perforated appendicitis and its attendant complications).<sup>38</sup> Conversely, time-consuming or unnecessary diagnostic workup (an important, but hard to operationalize outcome) may delay the indicated treatment and increase the risk of complications or result in false positive results and more “negative” appendectomies. Furthermore, diagnostic testing can impact resource utilization for the management of patients with acute abdominal pain. For example, examination with CT may reduce length of stay by avoiding prolonged observation in cases where a diagnosis cannot be established clinically or by eliminating the need for additional diagnostic testing.<sup>18</sup> In some cases, CT can also facilitate direct therapeutic intervention. For example, in patients with perforated appendicitis complicated by an abscess, the radiologist can not only detect but also treat the abscess by percutaneous drainage, thus avoiding the need for immediate operative intervention.

## **Special Considerations for the Diagnosis of RLQ Pain/Acute Appendicitis**

The diagnostic workup of acute appendicitis is complex because patients with acute abdominal pain of different etiologies can present with similar symptoms. Diagnosis is particularly challenging in children, women of reproductive age, pregnant women, and frail or elderly patients.<sup>8,39,40</sup>

### **Children**

Acute appendicitis in children is often diagnosed after perforation has occurred.<sup>41-43</sup> Children have a thinner appendiceal wall and less developed omentum (the largest peritoneal fold), and thus may not readily wall off a perforation. In addition, many common childhood illnesses have symptoms similar to those of early acute appendicitis (e.g., fever, nausea, and vomiting), making the differential diagnosis more challenging. Young children may have difficulty communicating about their discomfort or describing their symptoms, making the clinical examination less informative and leading to diagnostic delays.<sup>11</sup> In addition, the use of modalities that involve ionizing radiation (e.g., CT) possibly entails greater radiation-related risks for children.<sup>8</sup>

### **Women of Reproductive Age**

A large proportion of women of reproductive age with appendicitis are misdiagnosed.<sup>44</sup> Establishing a diagnosis in women of reproductive age with RLQ pain/suspected acute appendicitis can be particularly challenging because symptoms of acute appendicitis can mimic those of gynecologic disease (e.g., pelvic inflammatory disease, ectopic pregnancy, etc.).

### **Pregnant Women**

Diagnosis of suspected acute appendicitis in pregnant women can also be challenging because some symptoms of appendicitis (nausea and vomiting) are common in normal pregnancies and because enlargement of the uterus can alter the location of the appendix, which often moves higher and to the back.<sup>45</sup> Anatomic changes induced by pregnancy make the clinical examination of pregnant patients with abdominal pain more challenging and result in technical difficulties when using US.<sup>36,46,47</sup> Tests involving ionizing radiation (e.g., CT) are also generally avoided during pregnancy to prevent exposure of the fetus to radiation. Finally, obtaining a white blood cell count is generally not helpful in the diagnosis of acute appendicitis in pregnant women because leukocytosis is common during pregnancy. From a decisionmaking perspective, the management of suspected appendicitis in pregnant women is complicated by the need to balance the potential benefits and harms of testing for both the mother and the fetus.

### **Frail and Elderly Individuals**

The elderly typically present with appendicitis in more advanced stage, when compared to younger patients.<sup>48</sup> Older patients may delay seeking care, and definitive diagnosis is sometimes delayed further because competing etiologies for abdominal pain (e.g., malignancy or diverticulitis) are considered more likely. Therefore, the performance of diagnostic tests may be modified by patient age (e.g., US has been reported to have higher diagnostic performance in older patients) and by the more advanced disease stage that is common in this age group. Elderly

and frail individuals with appendicitis have a higher complication rate and a higher risk of mortality, compared to younger/less-frail patients.

## **Rationale for Evidence Review**

Accurate testing of patients with RLQ pain, or less typical presentations consistent with acute appendicitis, to identify those who need treatment can improve clinical outcomes and reduce resource utilization. Our review of guidelines and published systematic reviews indicated a lack of specific guidance for selecting diagnostic modalities, particularly in patient subgroups in whom the diagnosis is known to be particularly challenging (e.g., children, women of reproductive age, and pregnant women). Existing systematic reviews have not adequately investigated the comparative effectiveness of alternative diagnostic approaches (typically they assess a single diagnostic modality), have focused almost exclusively on test performance outcomes (without providing evidence on the impact of tests on intermediate or patient-relevant outcomes), and have not addressed factors that may modify the test performance (such as patients' age and sex, setting of care, or aspects of the test itself, e.g., the use of oral contrast, its administration via different routes, etc.). No review has comprehensively examined all tests of interest or focused on comparisons between alternative strategies.

## **Key Questions**

This review addresses the following Key Questions:

**Key Question 1:** What is the performance of alternative diagnostic tests, alone or in combination, for patients with right lower quadrant (RLQ) pain and suspected acute appendicitis?

1. What is the performance and comparative performance of alternative diagnostic tests in the following patient populations: children, adults, nonpregnant women of reproductive age, the elderly (age  $\geq 65$  years)?
2. What factors modify the test performance and comparative test performance of available diagnostic tests in these populations?

**Key Question 2:** What is the comparative effectiveness of alternative diagnostic tests, alone or in combination, for patients with RLQ pain and suspected acute appendicitis?

1. For the populations listed under Key Question 1a, what is the effect of alternative testing strategies on diagnostic thinking, therapeutic decisionmaking, clinical outcomes, and resource utilization?
2. What factors modify the comparative effectiveness of testing for patients with RLQ pain and suspected acute appendicitis?

**Key Question 3:** What are the harms of diagnostic tests per se, and what are the treatment-related harms of test-directed treatment for tests used to diagnose RLQ pain and suspected acute appendicitis?

## **Methods**

The methods for this systematic review follow the AHRQ “Methods Guide for Effectiveness and Comparative Effectiveness Reviews” (available at [www.effectivehealthcare.ahrq.gov/](http://www.effectivehealthcare.ahrq.gov/)); methods and results are reported in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) checklist.<sup>50</sup>

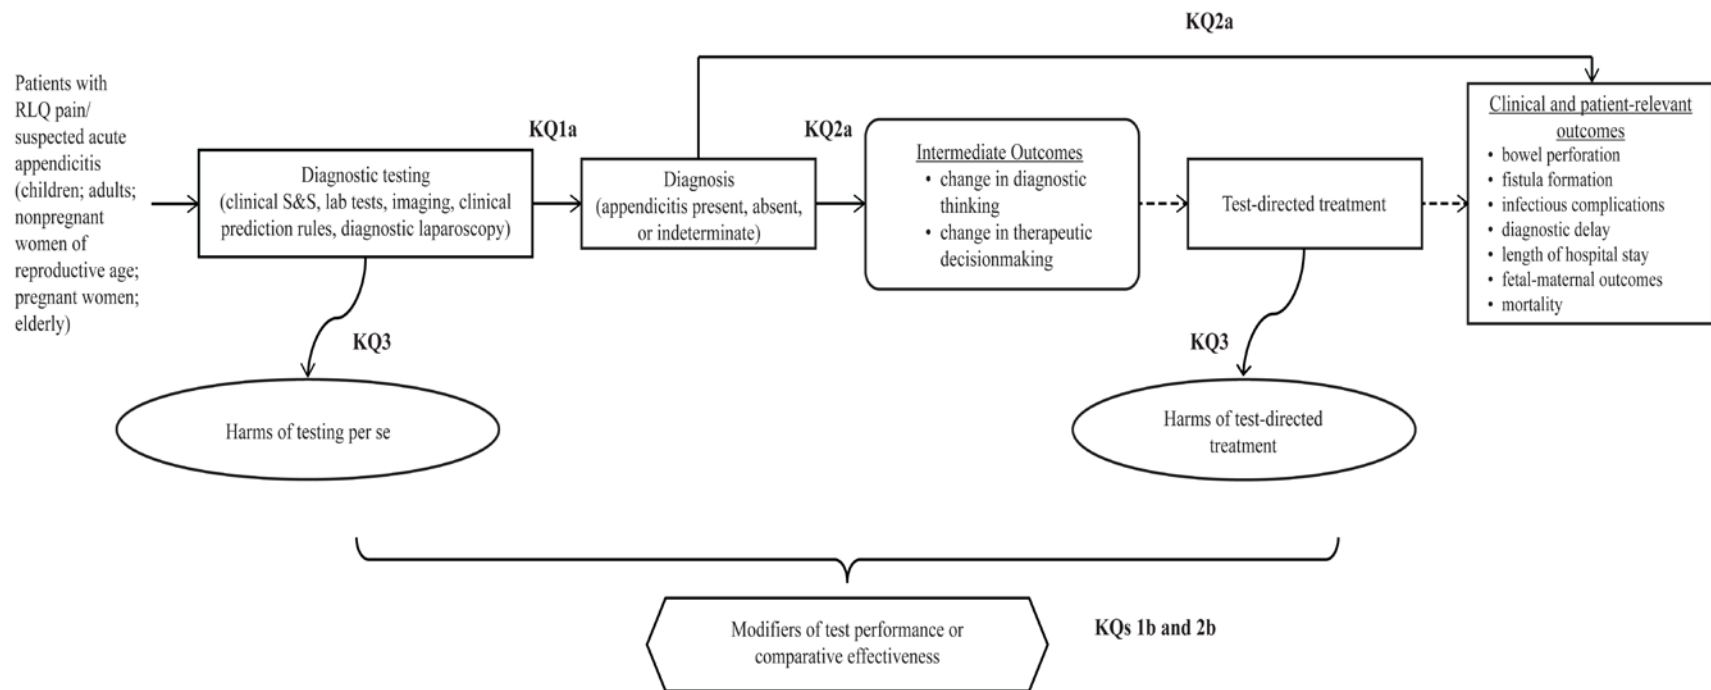

### **AHRQ Task Order Officer, Stakeholder Input, and Review Protocol**

The AHRQ Task Order Officer (TOO) was responsible for overseeing all aspects of this project. A panel of key informants gave input on the key questions (KQs) to be examined; these KQs were posted on AHRQ’s EHC website for public comment from April 17 to May 14, 2013 and revised in response to comments. We then drafted a protocol for the systematic review and recruited a panel of technical experts to provide high-level content and methodological input throughout the development of the review. The TEP included representatives of professional societies, experts in the diagnosis and treatment of RLQ abdominal pain and appendicitis (including emergency physicians, radiologists, and surgeons), and a patient representative. The finalized protocol is posted on the EHC Web site at <http://effectivehealthcare.ahrq.gov/ehc/products/528/1827/Appendicitis-protocol-131209.pdf>. The PROSPERO registration number for this review is CRD42013006480.

### **Analytic Framework**

We used an analytic framework (Figure 1) that maps the Key Questions within the context of populations, interventions, comparators, and outcomes of interest.

**Figure 1. Analytic framework**

KQ = Key Question; RLQ = right lower quadrant; S & S = symptoms and signs

## **Inclusion and Exclusion Criteria**

### **Populations and Conditions of Interest**

The population of interest for all Key Questions was patients with acute RLQ abdominal pain ( $\leq 7$  days duration) for whom appendicitis is considered in the differential diagnosis. Separate analyses were performed for the following populations:

- Children (age  $< 18$  years); we initially planned additional analyses for subgroups of very young children ( $< 2$  years and 2-5 years of age); however, data were inadequate for examining these subgroups
- Adults (age  $\geq 18$  years)
- Nonpregnant women of reproductive age
- Pregnant women
- Elderly (age  $\geq 65$  years)

### **Interventions**

For all Key Questions, the interventions of interest were diagnostic tests (alone or in combination) for diagnosing appendicitis, including clinical signs (e.g., psoas sign, obturator sign, Rovsing sign), clinical symptoms (e.g., fever, migrating pain, guarding), laboratory tests (e.g., white blood cell count, C-reactive protein concentration, left shift), multivariate diagnostic scores (including clinical prediction and decision rules, e.g., Alvarado score, Pediatric Appendicitis Score, other predictive models), imaging tests (e.g., US; multidetector or helical CT with or without contrast administered orally, rectally, or intravenously, MRI with or without contrast; abdominal X-ray); nuclear imaging studies; and diagnostic laparoscopy.

### **Comparators (Index and Reference Standard Tests)**

For all Key Questions, the comparators were alternative tests or test combinations (as listed above) or clinical observation.

### **Outcomes**

For Key Question 1, the outcome of interest was test performance, as assessed by sensitivity, specificity, or other measures of accuracy; using pathology or clinical followup as the reference standard. For Key Question 2, we looked for the following outcomes: impact on diagnostic thinking (e.g., change in diagnosis after testing; change in subsequent diagnostic approach after obtaining initial test results) and impact on therapeutic decisionmaking (e.g., change in treatment plan after testing; time from admission to surgery). We also looked at the following patient-centered and resource utilization outcomes: “negative” appendectomy rate, bowel perforation (ruptured appendix), fistula formation, infectious complications (abscess formation, peritonitis, sepsis, stump appendicitis), delay in diagnosis (time from presentation to definitive diagnosis; time from presentation to initiation of treatment; time from presentation to resolution of pain), length of hospital stay, fetal/maternal outcomes (for pregnant women; including premature labor, pregnancy loss, fetal morbidity, fetal mortality, maternal morbidity, maternal mortality), and mortality. For Key Question 3, we considered adverse effects of interventions, including direct harms of testing (e.g., harms from exposure to ionizing radiation, allergic reactions/kidney injury caused by contrast agents) harms of test-directed treatment (indirect).

When outcome definitions were not provided by the included studies, we adopted the terms used by the studies at face value.

## **Timing**

Studies were considered regardless of duration of followup.

## **Setting**

All health care settings were considered.

## **Study Design and Additional Criteria**

Given the large expected number of potentially relevant studies to be reviewed in full text, the scope of the project had to be constrained operationally to ensure feasibility. Several approaches that could be used to achieve this aim were discussed with Key Informants during Topic Refinement and the TEP members (in preparation of this protocol). Based on these discussions and preliminary literature scans, we opted to use the following approach:

- For studies assessing test performance outcomes (i.e. for a subset of the studies pertaining to Key Question 1), we relied on previously completed systematic reviews (when available) to identify relevant studies and obtain specific data items (see following paragraph). We updated these reviews to include more recent studies identified through literature searches.
- For index tests where no relevant systematic review of test performance meeting our selection criteria (see following paragraph) could be identified, we performed a de novo systematic review.
- For studies that directly compare alternative tests (for all outcomes of interest) and for studies (comparative or noncomparative) reporting outcomes other than test performance (e.g., change in diagnostic thinking, impact on therapeutic decisionmaking, clinical outcomes, and harms) we performed a de novo review, because these topics were not addressed adequately by the reviews that were available when we designed our protocol.

We used existing systematic reviews to identify studies with test performance outcomes (Key Question 1). Systematic reviews were considered as potential sources of eligible studies if they met the following criteria:

- Reported the bibliographic databases searched and any additional sources of included studies.
- Used explicit criteria for selecting primary studies of the populations and index tests of interest (as described in section 2, above).
- Examined test performance outcomes.
- Provided a list of included studies that allowed the retrieval of the corresponding full text publications.

## **Literature Search and Abstract Screening**

Appendix A describes our literature search strategies. Searches were conducted in PubMed<sup>®</sup>, EMBASE<sup>®</sup>, the Cochrane Central Register of Controlled Trials, and the Cumulative Index to Nursing and Allied Health Literature (CINAHL<sup>®</sup>) databases to identify primary research studies meeting our criteria (last search on August 6, 2014, for PubMed; August 12, 2014, for all other

databases). We also used the PubMed<sup>®</sup> search results to identify systematic reviews of the tests of interest (last search July 31, 2013; the search for systematic reviews was not updated because our search for primary studies covered recent years adequately). We did not restrict searches by year of publication. A common set of 200 abstracts (in 2 pilot rounds, each with 100 abstracts) were screened by all reviewers, and discrepancies were discussed in order to standardize screening practices and ensure understanding of screening criteria by all team members. The remaining citations were split into nonoverlapping sets, each screened by two reviewers independently. Discrepancies were resolved by consensus involving a third investigator.

## **Study Selection and Eligibility Criteria**

Potentially eligible citations (i.e., abstracts considered potentially relevant by consensus) were obtained in full text and reviewed for eligibility on the basis of the predefined inclusion criteria. A single reviewer examined all articles; a second reviewer examined a subset of 350 articles independently. Disagreements regarding article eligibility were resolved by consensus involving a third reviewer.

We included only English-language studies during full text review because our preliminary searches indicated that non-English-language studies had small sample sizes and represented a small proportion of the evidence for any given test modality; as such, their exclusion is unlikely to have affected our conclusions. We excluded studies published exclusively in abstract form (e.g., conference proceedings) because they are typically not peer reviewed, only partially report results, and may change substantially when fully published. The lists of included and excluded studies (organized by reason for exclusion) are in Appendix B.

We asked the TEP to provide citations of potentially relevant articles. Additional studies were identified through the perusal of reference lists of eligible studies, published clinical practice guidelines, relevant narrative and systematic reviews, conference proceedings, and Scientific Information Packages from manufacturers. All articles identified through these sources were screened for eligibility against the same criteria as for articles identified through literature searches. The final list of included studies was reviewed by the TEP to ensure that no key publications had been missed.

## **Data Abstraction and Management**

Previously published reviews were used as sources of eligible single index test studies of test performance and as sources of data for objective data elements from these studies (bibliographic study information, characteristics of included populations, and counts of individuals stratified by diagnostic test result and disease status). For all studies, EPC investigators extracted data elements using standardized operational definitions (e.g., elements of study design, risk of bias assessment) from the full text of primary study publications.

Data was extracted into Word or Excel data extraction forms and will be uploaded to the Systematic Review Data Repository (SRDR, <http://srdr.ahrq.gov/home/index>) upon submission of the Final Report. The forms included elements that address population characteristics, sample size, study design, descriptions of the index and reference standard tests of interest, analytic details, and outcome data. We pilot tested the forms on several studies extracted by all team members to ensure consistency in operational definitions.

A single reviewer extracted data from each eligible study of test performance; one reviewer extracted and a second reviewer verified data from NRCSs and RCTs. For RCTs, when possible, data were extracted according to the intention-to-treat principle. We verified the data extraction

and risk of bias assessment in a random sample of 368 non-comparative test performance studies (reporting 1487 separate pairs of sensitivity and specificity). Overall, we found that agreement was excellent in capturing information about the index and reference standard tests and numerical information on test performance. Agreement was less good for some risk of bias items (complete and non-differential verification and inappropriate exclusions). These items were re-extracted for all included studies following a series of standardization exercises to ensure consistent application of our operational definitions.

We contacted authors (a) to clarify information reported in the papers that is hard to interpret (e.g., inconsistencies between tables and text); (b) to obtain missing data on key subgroups of interest when not available in the published reports (e.g., pregnant women, women of reproductive age, children); and (c) to verify suspected overlap between study populations in publications from the same group of investigators. Author contact was by email (to the corresponding author of each study), with a primary contact attempt (once all eligible studies had been identified) and up to two reminder emails (approximately 2 and 4 weeks after the first attempt).

## **Assessment of the Risk of Bias of Individual Studies**

We assessed the risk of bias for each individual study using the assessment methods detailed by the AHRQ Methods Guide. We used items from the updated QUADAS 2 instrument to assess the risk of bias of the diagnostic test studies included in the review (these studies comprised the majority of the available studies).<sup>51-54</sup> The items we selected assessed four domains for risk of bias related to patient selection, use of the index test, use of the reference standard test, and patient flow and timing. For studies of other designs, we used appropriate sets of items to assess risk of bias: for NRCSSs, we used items from the Newcastle-Ottawa scale;<sup>55</sup> for RCTs, we used items from the Cochrane Risk of Bias tool.<sup>56</sup>

We did not calculate “composite” quality scores. Instead, we assessed and reported each methodological quality item (as Yes, No, or Unclear/Not Reported) for each eligible study. We rated each study as being of low, intermediate, or high risk of bias on the basis of adherence to accepted methodological principles. Generally, studies with low risk of bias have the following features: lowest likelihood of confounding due to comparison to a randomized controlled group; a clear description of the population, setting, interventions, and comparison groups; appropriate measurement of outcomes; appropriate statistical and analytic methods and reporting; no reporting inconsistencies; clear reporting of dropouts, and a dropout rate less than 10 percent; and no other apparent source of bias. Studies with moderate risk of bias are susceptible to some bias but not sufficiently to invalidate results. They do not meet all the criteria for low risk of bias owing to some deficiencies, but none are likely to introduce major bias. Studies with moderate risk of bias may not be randomized or may be missing information, making it difficult to assess limitations and potential problems. Studies with high risk of bias are those with indications of bias that may invalidate the reported findings (e.g., observational studies not adjusting for any confounders, studies using historical controls, or studies with very high dropout rates). These studies have serious errors in design, analysis, or reporting and contain discrepancies in reporting or have large amounts of missing information. We discuss the handling of high risk of bias studies in the following sections.

In quantitative analyses, we performed subgroup analyses to assess the impact of each risk of bias item on the meta-analytic results. The grading was outcome specific, such that a given study that reports its primary outcome well but did an incomplete analysis of a secondary outcome was

graded of different quality for the two outcomes. Studies of different designs were graded within the context of their study design.

## Evidence Synthesis

We summarized the included studies qualitatively and present important features of the study populations, designs, interventions, outcomes, and results in summary tables. Population characteristics of interest include age, sex, duration of symptoms, and clinical presentation at enrollment. Design characteristics include methods of population selection and sampling, and follow-up duration. Test characteristics include aspects specific to each diagnostic test of interest (e.g., the use and route of administration of contrast agents for imaging tests), the specific definitions of clinical signs, and the components and their weights for clinical prediction rules (the surgical approach for diagnostic laparoscopy, etc.). We present information on test performance, harms, intermediate and terminal outcomes, and resource utilization. Of note, all studies evaluating the test performance of the same single index test in a similar patient population were synthesized jointly, regardless of their source (our own literature searches or previously published reviews).

For each comparison of interest, we judged whether the eligible studies were sufficiently similar to be combined in a meta-analysis on the basis of clinical heterogeneity of patient populations and testing strategies, as well as methodological heterogeneity of study designs and outcomes reported. We performed analyses appropriate for the specific role of testing evaluated in each study (replacement, triage, add-on) whenever possible.<sup>57</sup> However, the complexity of the differential diagnosis of RLQ pain and limited reporting of relevant information in published studies limited our ability to distinguish between alternative test roles.

Studies employed a variety of different diagnostic methods (e.g., different imaging modalities, clinical symptoms and signs, laboratory measurements, and combinations thereof). We have based our judgments on the similarity of available tests on technical descriptions of the modalities used in each study (e.g., whether studies used similar imaging technologies or similar clinical examination protocols). We sought input from TEP members to define groups of “sufficiently similar” studies for synthesis (including meta-analysis) during later stages of the review as questions arose. Of note, the material used to solicit TEP input did not include any data on outcome results extracted from the studies (to limit the potential for bias). The determination on the appropriateness of meta-analysis was made before any data analysis. We did not base the decision to perform a meta-analysis on statistical criteria for heterogeneity. Such criteria are often inadequate (e.g., low power when the number of studies is small) and do not account for the ability to explore and explain heterogeneity by examining study-level characteristics. Instead, we used clinical criteria to assess study exchangeability (e.g., we considered whether studies enrolled populations selected using similar inclusion criteria, with comparable baseline risk of appendicitis, and assessed using similar imaging technologies or other tests). The main analyses include all relevant studies.

Analyses were performed separately for the following patient populations: children, women of reproductive age, pregnant women, and the elderly. Subgroup analyses (e.g., by clinical presentation at diagnosis, aspects of specific test modalities, etc.) were also performed. The concordance of findings across subgroup analyses was evaluated qualitatively (in all instances) and quantitatively (using meta-regression, when the data allowed). We considered the following potential modifiers of test performance or other outcomes in meta-regression analyses: patient characteristics (e.g., age, sex, clinical presentation at enrollment), test characteristics (e.g., extent

of imaging field, use of contrast agents and route of administration), clinician and facility factors (e.g., setting of test use), and date of publication ( $\geq 2005$  vs. earlier). We also performed subgroup analyses by individual risk of bias items to assess the impact of each risk of bias item on the results of the meta-analysis. We evaluated the robustness of our findings in sensitivity analyses that exclude studies at high risk of bias. Some studies examining the test performance of imaging tests reported classification results from multiple raters. In our main analyses we used results from the rater that had the highest sum of sensitivity plus specificity (i.e., the rater that had a sum of estimated sensitivity and specificity closest to 2). As a worst-case sensitivity analysis we also repeated all analyses using results from the rater that had the lowest sum of sensitivity plus specificity. In addition, some studies of imaging tests reported information on indeterminate test results (in some cases separately by final diagnostic status, in other cases without any information on final diagnosis). In our main analyses, indeterminate test results were excluded. To explore the impact of indeterminate results on test performance we performed two “extreme case” sensitivity analyses, one where all indeterminate results with unknown (not reported) final diagnostic status were considered false positive and one where all were considered false negative. In these sensitivity analyses, all indeterminate results with known diagnostic status were considered in the corresponding false result category (i.e., indeterminate results in patients with a final diagnosis of appendicitis were considered false negative and indeterminate results in unaffected individuals were considered false positive).<sup>58</sup>

When five or more sufficiently similar studies evaluated the test performance of the same test in the same population, we used a bivariate-bivariate normal meta-analysis model to obtain summary sensitivity and specificity estimates.<sup>59,60</sup> We used the summary sensitivity and specificity estimates to calculate summary positive and negative likelihood ratios (LRs).<sup>61</sup> We also used the estimates from the bivariate model to construct summary receiver operating characteristic (ROC) curves using the model proposed by Rutter and Gatsonis.<sup>62,63</sup> For parallel arm studies comparing alternative test strategies with respect to clinical outcomes and resource utilization, we planned to perform meta-analyses when there were more than three unique, sufficiently similar studies evaluating the same intervention and comparator and reporting the same outcomes; however, no such instances were identified. All meta-analyses were conducted using Bayesian methods with flat (uninformative) priors;<sup>64</sup> models were fit with Markov chain Monte Carlo methods. Sensitivity analyses (including leave-one-out analyses, analyses assuming a fixed effects model, and reanalyses after excluding a group of studies) were undertaken where considered appropriate (e.g., in the presence of studies with outlying effect sizes or evidence of temporal changes in effect sizes). Heterogeneity was assessed visually by inspecting plots of study estimates in the ROC space and by examining the posterior distribution of the between-study heterogeneity parameters (for logit-sensitivity and logit-specificity). We explored between-study heterogeneity using subgroup and meta-regression analyses, by extending the binomial-bivariate normal model to include study-level covariates.

In cases when only a subset of the available studies could be quantitatively combined (e.g., when some studies are judged to be so clinically different from others as to be excluded from meta-analysis), we synthesized findings across all studies qualitatively by taking into account the magnitude and direction of effects and estimates of performance.

## Grading the Strength of Evidence

We followed the Methods Guide<sup>49</sup> to evaluate the strength of the body of evidence for each Key Question with respect to the following domains: risk of bias, consistency, directness,

precision, and reporting bias.<sup>49,65</sup> Briefly, we defined the risk of bias (low, medium, or high) on the basis of the study design and the methodological quality of the studies. Generally, lack of studies at low risk of bias or inconsistencies among groups of studies at different levels of risk of bias led to downgrading the strength of the evidence. We rated the consistency of the data as no inconsistency, inconsistency present, or not applicable (if there is only one study available). We did not use rigid counts of studies as standards of evaluation (e.g., four of five studies agree, therefore the data are consistent); instead, we assessed the direction, magnitude, and statistical significance of all studies and made a determination. We describe our logic where studies are not unanimous. We assessed directness of the evidence (“direct” vs. “indirect”) on the basis of the use of surrogate outcomes or the need for indirect comparisons. We assessed the precision of the evidence as precise or imprecise on the basis of the degree of certainty surrounding each effect estimate. A precise estimate is one that allows for a clinically useful conclusion. An imprecise estimate is one for which the confidence interval is wide enough to include clinically distinct conclusions and that therefore precludes a conclusion.

The majority of studies to be included in this review are observational cohorts, reporting on outcomes of test performance, utilizing one or more index tests on all study participants. However, we found a small number of parallel group, randomized or non-randomized, comparative studies of alternative test strategies (e.g., reporting comparisons between alternative tests). We did not combine the results of randomized and non-randomized studies statistically. Instead, we qualitatively evaluated similarities and differences in study populations, diagnostic methods, and outcomes among study designs. These comparisons inform our judgments on applicability of study findings to clinical practice.

The potential for *reporting bias* (“suspected” vs. “not suspected”) was evaluated with respect to publication bias, selective outcome reporting bias, and selective analysis reporting bias. For reporting bias, we made qualitative dispositions rather than perform formal statistical tests to evaluate differences in the effect sizes between more precise (larger) and less precise (smaller) studies. Although these tests are often referred to as tests for publication bias; reasons other than publication bias can lead to a statistically significant result, including “true” heterogeneity between smaller and larger studies, other biases, and chance, rendering the interpretation of the tests nonspecific and the tests noninformative.<sup>66,67</sup> Therefore, instead of relying on statistical tests, we evaluated the reported results across studies qualitatively, on the basis of completeness of reporting (separately for each outcome of interest), number of enrolled patients, and numbers of observed events. Judgment on the potential for selective outcome reporting bias was based on reporting patterns for each outcome of interest across studies. We acknowledge that both types of reporting bias are difficult to reliably detect on the basis of data available in published research studies (i.e., without access to study protocols and detailed analysis plans). Because such assessments are inherently subjective, we explicitly present all operational decisions and the rationale for our judgment on reporting bias in the Results and Discussion sections.

Finally, we rated the strength of the body of evidence using four levels: high, moderate, low, and insufficient.<sup>49</sup> These describe our level of confidence that the evidence reflects the true effect for the major comparisons of interest.

## Assessing Applicability

We followed the Methods Guide<sup>49</sup> to evaluate the applicability of included studies to patient populations of interest. We evaluated studies separately by important clinical subgroups: children, women of reproductive age, pregnant women, and the elderly. Applicability to the

population of interest was also judged separately on the basis of duration of symptoms before enrollment, outcomes (e.g., test performance, impact on diagnostic thinking and clinical decisionmaking, clinical outcomes), and setting of care (e.g., whether patients were recruited in an academic, tertiary, or primary care setting).

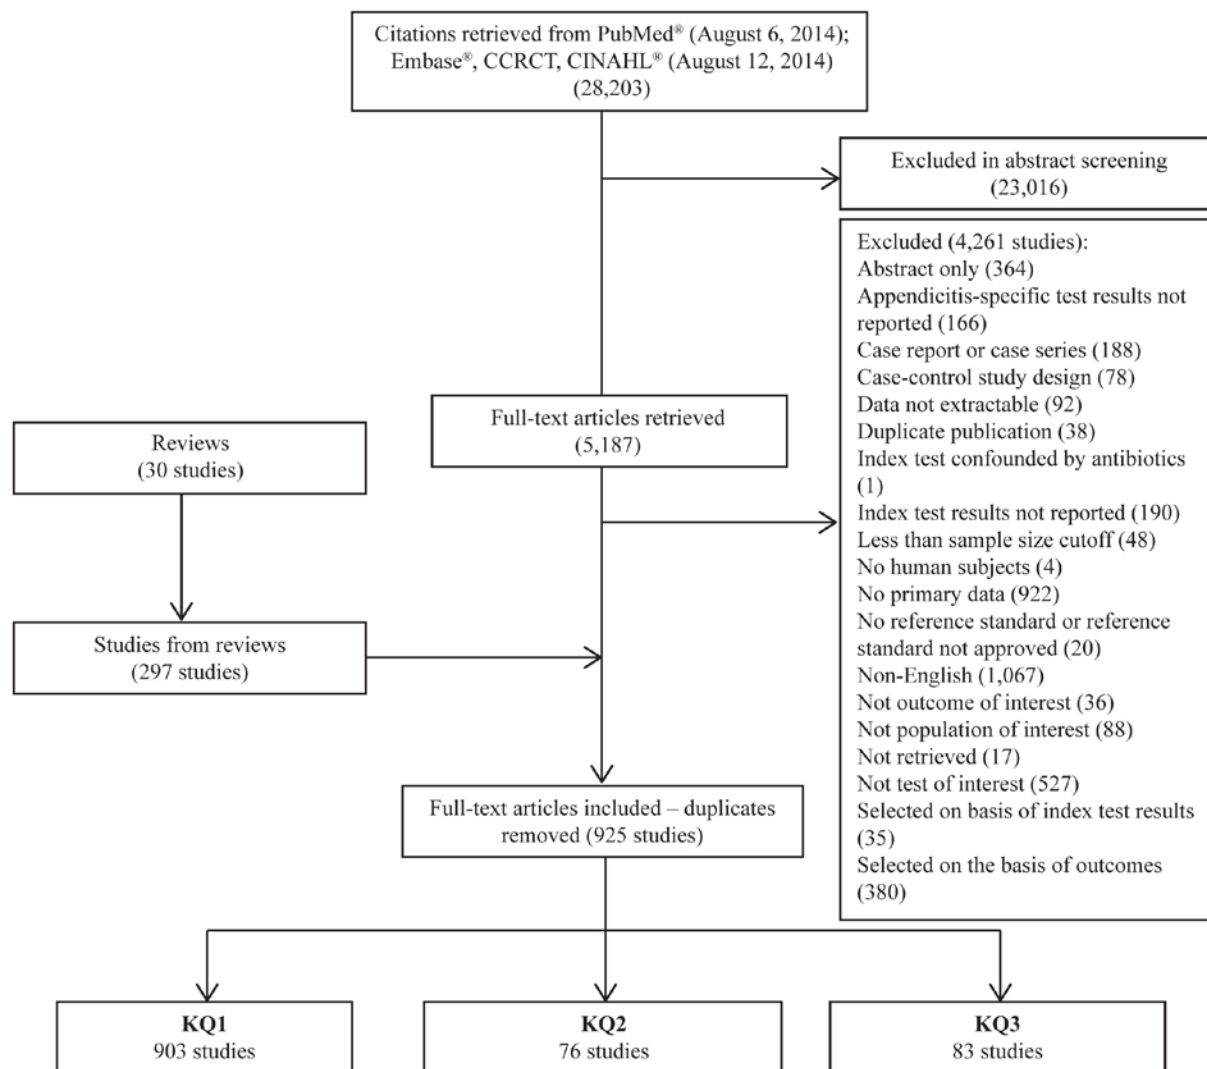

## **Peer Review**

The initial draft report was pre-reviewed by the TOO and an AHRQ Associate Editor. Following revisions, the draft report was sent to invited peer reviewers and was simultaneously uploaded to the AHRQ Web site where it was available for public comment for 30 days. All reviewer comments (both invited and from the public) were collated and individually addressed. The revised report and the EPC's responses to invited and public reviewers' comments were again reviewed by the TOO and Associate Editor prior to completion of the report. The authors of the report had final discretion as to how the report was revised based on the reviewer comments, with oversight by the TOO and Associate Editor. A disposition of comments report will be made available online, 3 months after the Agency posts the final systematic review on the EHC Web site.

## Results

Our searches for systematic reviews retrieved 699 citations. After review of abstracts, 58 of these citations were deemed potentially relevant and the corresponding full-length articles were obtained and examined in full text. After full-text review, 30 systematic reviews were considered eligible, and provided information on 297 potentially relevant primary studies on the diagnosis of acute appendicitis. Our literature searches for primary studies retrieved 28,203 citations. Based on abstract review, 5187 of these citations were considered potentially relevant and were retrieved in full text. Our search strategies for all databases are presented in Appendix A; the complete lists of included and excluded studies (organized by reason for exclusion) are presented in Appendix B. After full-text review, 925 primary studies were considered eligible (630 of which had not been included in previous reviews – mainly because they had been published after last search date of the reviews). Figure 2 presents the literature flow.

**Figure 2. Flow chart of included studies**

CCRCT = Cochrane Central Register of Controlled Trials; KQ = Key Question

**Key Question 1: What is the performance of alternative diagnostic tests, alone or in combination, for patients with right lower quadrant (RLQ) pain and suspected acute appendicitis?**

## **Included Studies With Information on Test Performance**

In total, 903 studies, published between 1956 and 2014, met the inclusion criteria for Key Question 1. We organized studies into five categories based on the tests they evaluated: clinical symptoms and signs (137 studies), laboratory tests (217 studies), imaging tests (519 studies), multivariable diagnostic scores (127 studies), and diagnostic laparoscopy (55 studies). Appendix C contains a list of all included studies for this Key Question, with information on the tests examined in each study, test performance data, a summary of study characteristics, and details of our risk of bias assessment. In this section we summarize information on tests that were examined most often in the studies we reviewed and those that, based on our reading of the literature, and discussions with Key Informants and Technical Experts, were thought to be more clinically relevant.

Results for each test category (and each test) are presented separately for adults, children, women of reproductive age, pregnant women (some studies reported results for more than one of these subgroups), and mixed populations (typically including male and female patients of all ages). When five or more independent studies had evaluated the same test in the same population subgroup, we conducted meta-analyses of test performance using a binomial-bivariate normal random effects model. Results from these analyses are presented as summary sensitivity and specificity estimates, and corresponding positive and likelihood ratios (with 95% central CrIs).<sup>a</sup>

## **Test Performance of Clinical Symptoms and Signs (in Isolation)**

One hundred and thirty seven studies, published between 1976 and 2014, provided information on the performance of clinical symptoms and signs for the diagnosis of acute appendicitis. Commonly examined symptoms included right lower quadrant abdominal pain, anorexia, nausea and vomiting, and fever. Commonly examined signs included guarding, tenderness (including rebound tenderness), rigidity, and other signs indicative of peritoneal

---

<sup>a</sup>To aid in the interpretation of likelihood ratios we remind readers that these statistics can be used to convert pre-test probabilities to post-test probabilities. For example, before testing, assume that a patient has probability of disease

$$pre\text{-}test\ p = 0.1 \text{ and } pre\text{-}test\ odds = \frac{pre\text{-}test\ p}{1 - pre\text{-}test\ p} = \frac{0.1}{0.9} = 0.11 . \text{ If the diagnostic test has a positive likelihood}$$

ratio ( $LR^+$ ) of 15 then the post-test odds are  $post\text{-}test\ odds = pre\text{-}test\ odds \times LR^+ = 0.11 \times 15 = 1.67$  . This

$$\text{corresponds to a post-test probability of } post\text{-}test\ p = \frac{post\text{-}test\ odds}{post\text{-}test\ odds + 1} = \frac{1.67}{1.67 + 1} = 0.625 \text{ (i.e. the post-test}$$

probability is approximately 6 times greater than the pre-test value). If the test results had been negative and the test had a negative likelihood ratio ( $LR^-$ ) of 0.1, the post-tests odds would be

$$post\text{-}test\ odds = pre\text{-}test\ odds \times LR^- = 0.11 \times 0.1 = 0.011 , \text{ which corresponds to } post\text{-}test\ p = \frac{0.011}{0.011 + 1} = 0.011$$

(i.e., the post-test probability is approximately 10 times lower than the pre-test value). As a rule of thumb,

$LR^+ > 10$  and  $LR^- < 0.1$  are generally considered clinically meaningful.

inflammation. Table 1 presents a summary of the descriptive characteristics of the studies. Table 2 presents a summary of items related to study risk of bias. Studies were at moderate to high risk of bias. Blinding of index test and reference standard assessors were either not used or relevant information was not reported; the definition of a positive index test was often not provided; and most studies had differential verification. Table 3 presents a summary of the test performance results for clinical symptoms and signs. In general, their performance was limited. Almost all tests had positive likelihood ratios lower than 3 (no test had a positive likelihood ratio higher than 6) and most tests had negative likelihood ratios higher than 0.2. Figure 3 (parts 1 through 3) presents study results and summary ROC curves for selected clinical symptoms and signs. There was substantial heterogeneity in sensitivity and specificity for most tests; however, in most cases summary ROC lines appeared to fit the data relatively well (indicating that some of the heterogeneity may be due to threshold effects). Figure 4 shows the positive and negative predictive value for selected clinical symptoms and signs, over appendicitis prevalence.

**Table 1. Descriptive characteristics for studies evaluating clinical symptoms and signs for the diagnosis of acute appendicitis**

Patient Population	N Studies (Median N Patients/Affected/ Unaffected)	Median % of Women	Median of Average Age (Yrs)	Community Setting	Ambulatory Setting	Surgical Cohort	Clinical Presentation Consistent With Appendicitis	Median % of Patients With Perforation

LR = likelihood ratio; N = number; RLQ = right lower quadrant; RUQ = right upper quadrant; yrs = years.

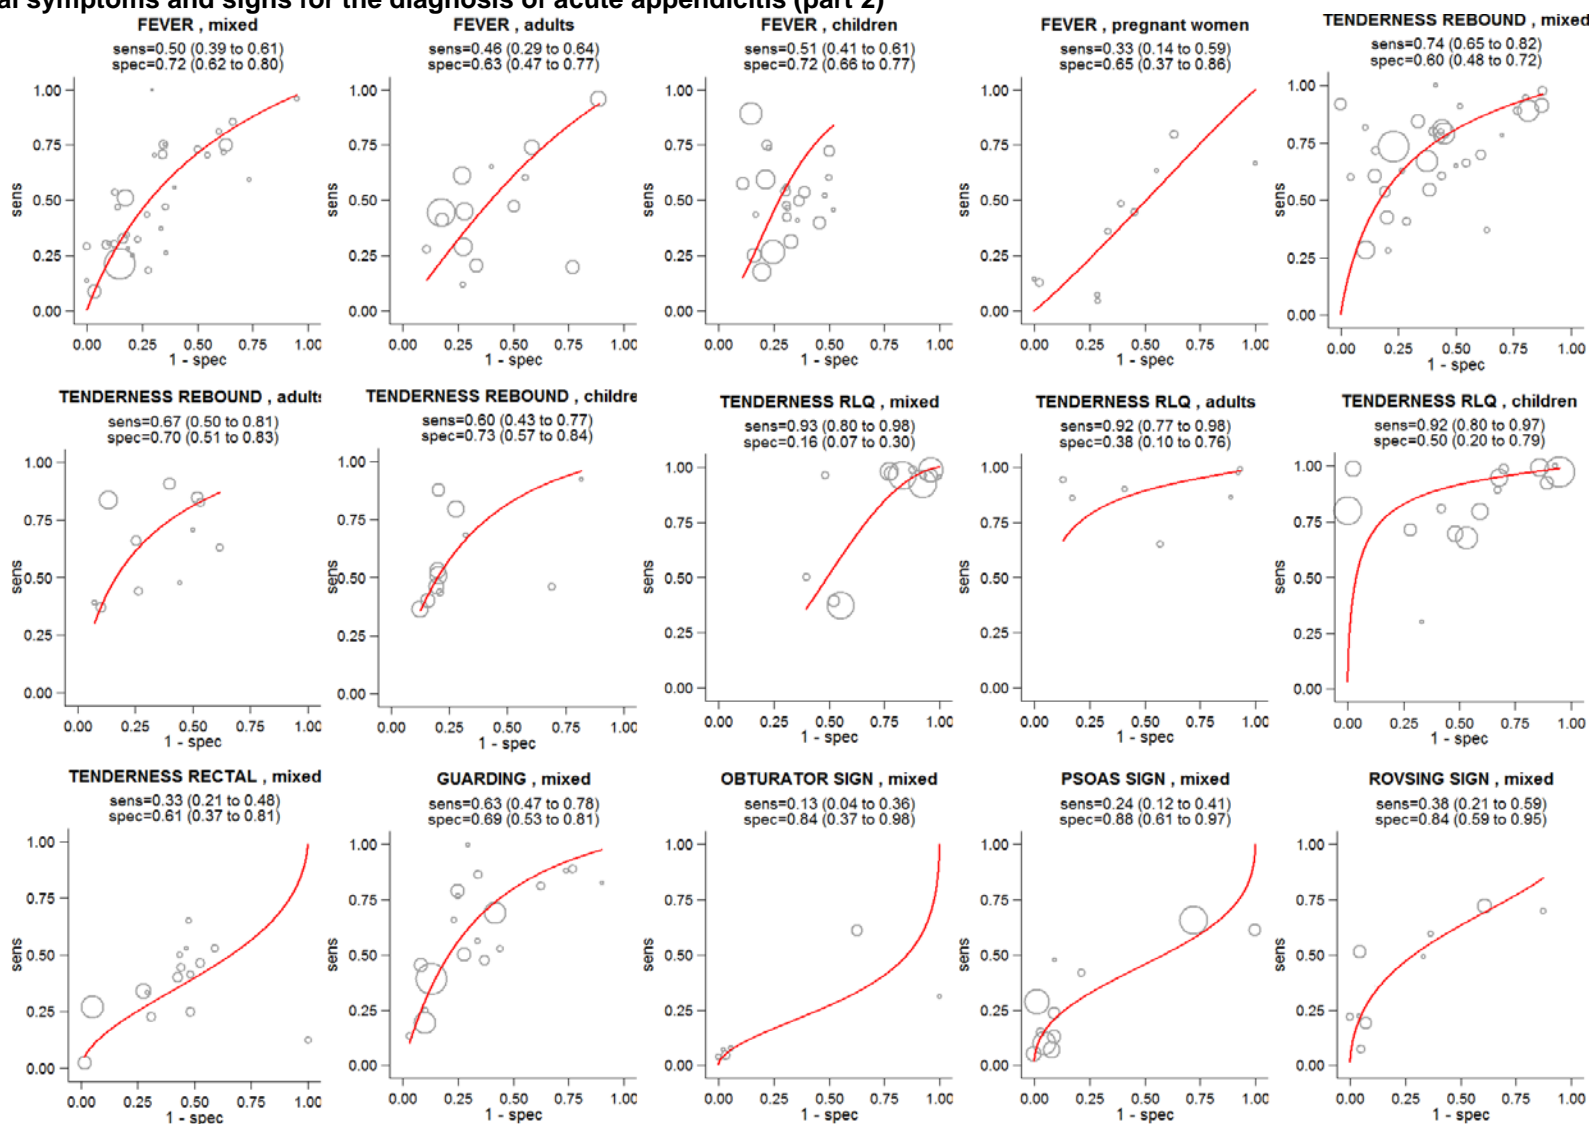

Sensitivity, specificity, and LR values are medians and 95% central credible intervals when 5 or more studies were available; medians and minimum to maximum values are reported when <5 studies were available; when a single study was available we report the estimate from that study.

RLQ = right lower quadrant; RUQ=right upper quadrant

## **Factors That Affect the Test Performance of Clinical Symptoms and Signs**

The vast majority of studies did not report adequate data to assess factors that may affect test performance (i.e., based on within study comparisons); for this reason we relied on comparisons across studies (via meta-regression analyses) to identify factors that may affect test performance. Table 4 summarizes the results of meta-regression analyses for various factors that may affect the performance of clinical signs for the diagnosis of acute appendicitis. Overall, no distinct pattern emerged to establish a particular factor as a modifier of test performance. Recent studies tended to produce lower estimates of summary sensitivity (published from 2005 onwards), often but not always associated with higher estimates of specificity. Yet, for all factors examined but CrIs were wide, indicating substantial uncertainty regarding the relative test performance of tests over levels of the modifiers we examined.

## **Impact of Risk of Bias Items on Estimated Test Performance of Clinical Symptoms and Signs**

Table 5 summarizes the results of meta-regression analyses for various factors that may affect the performance of clinical symptoms and signs tests for the diagnosis of acute appendicitis. In some cases items related to study risk of bias appeared to be associated with worse test performance of various clinical symptoms and signs. Specifically, nondifferential verification was associated with lower sensitivity in studies of fever in mixed populations; blinding of reference standard assessors was associated with lower specificity in studies of pain migration in mixed populations; complete verification was associated with lower sensitivity in studies of rebound tenderness in mixed populations; and blinding of index test assessors was associated with lower sensitivity in studies of rebound tenderness in mixed populations.

These results that study conduct may have affected estimates of test performance in meta-analyses of clinical symptoms and signs. However, our analyses relied on information that was often poorly reported in the primary studies and meta-regression results were often imprecise, indicating substantial uncertainty. The aforementioned differences were the only cases when CrIs did not include the null value among the large number of comparisons summarized in Table 5. Because each risk of bias item was examined individually, and because different items may be correlated between them and with other study characteristics that may affect performance estimates, we do not believe that definitive conclusions about specific items can be reached.

N = number; pts. = patients; ref. std. = reference standard; RLQ = right lower quadrant; RUQ = right upper quadrant

Sensitivity, relative sensitivity, specificity, and relative specificity values are medians and 95% central credible intervals when 5 or more studies were available; medians and minimum to maximum values are reported when <5 studies were available; when a single study was available we report the estimate from that study.

## Test Performance of Laboratory Tests

Two hundred and seventeen studies, published between 1956 and 2014, provided information on the test performance of laboratory tests for the diagnosis of acute appendicitis. Commonly evaluated tests included the white blood cell count, measures based on the blood count and differential, and serum C-reactive protein concentration. Table 6 presents a summary of the descriptive characteristics of the studies reporting information on laboratory tests. Table 7 presents a summary of key items related to study risk of bias. Studies were at moderate to high risk of bias. Blinding of the reference standard assessors was either not used or relevant information was not reported; a large proportion of studies had differential verification. Table 8 presents a summary of the test performance results for clinical symptoms and signs. In general, the performance of individual laboratory tests was rather poor; however, it was better than that of clinical symptoms and signs. Almost all laboratory tests had positive likelihood ratios lower than 3 (no test had a summary positive likelihood ratio higher than 5) and most tests had negative likelihood ratios higher than 0.2. Figure 5 presents study results and summary ROC curves for selected laboratory tests. There was substantial heterogeneity in sensitivity and specificity for most tests; however, in most cases summary ROC lines appeared to fit the data relatively well. Figure 6 shows the positive and negative predictive value for selected laboratory tests, over appendicitis prevalence.

**Table 6. Descriptive characteristics for studies evaluating laboratory tests for the diagnosis of acute appendicitis**

Patient Population	N studies (Median N Patients/Affected/ Unaffected)	Median % of Women	Median of Average Age (Yrs)	Community Setting	Ambulatory Setting	Surgical Cohorts	Clinical Presentation Consistent With Appendicitis	Median % of Patients With Perforation
Adults	38 (134/73/29)	44.2%	29.4	10.5%	21.1%	52.6%	92.1%	11.9%

CRP = c-reactive protein; ESR = erythrocyte sedimentation rate; IL-6 = interleukin 6; LR = likelihood ratio; N = number; PMNC = polymorphonuclear count; WBC = white blood cell count

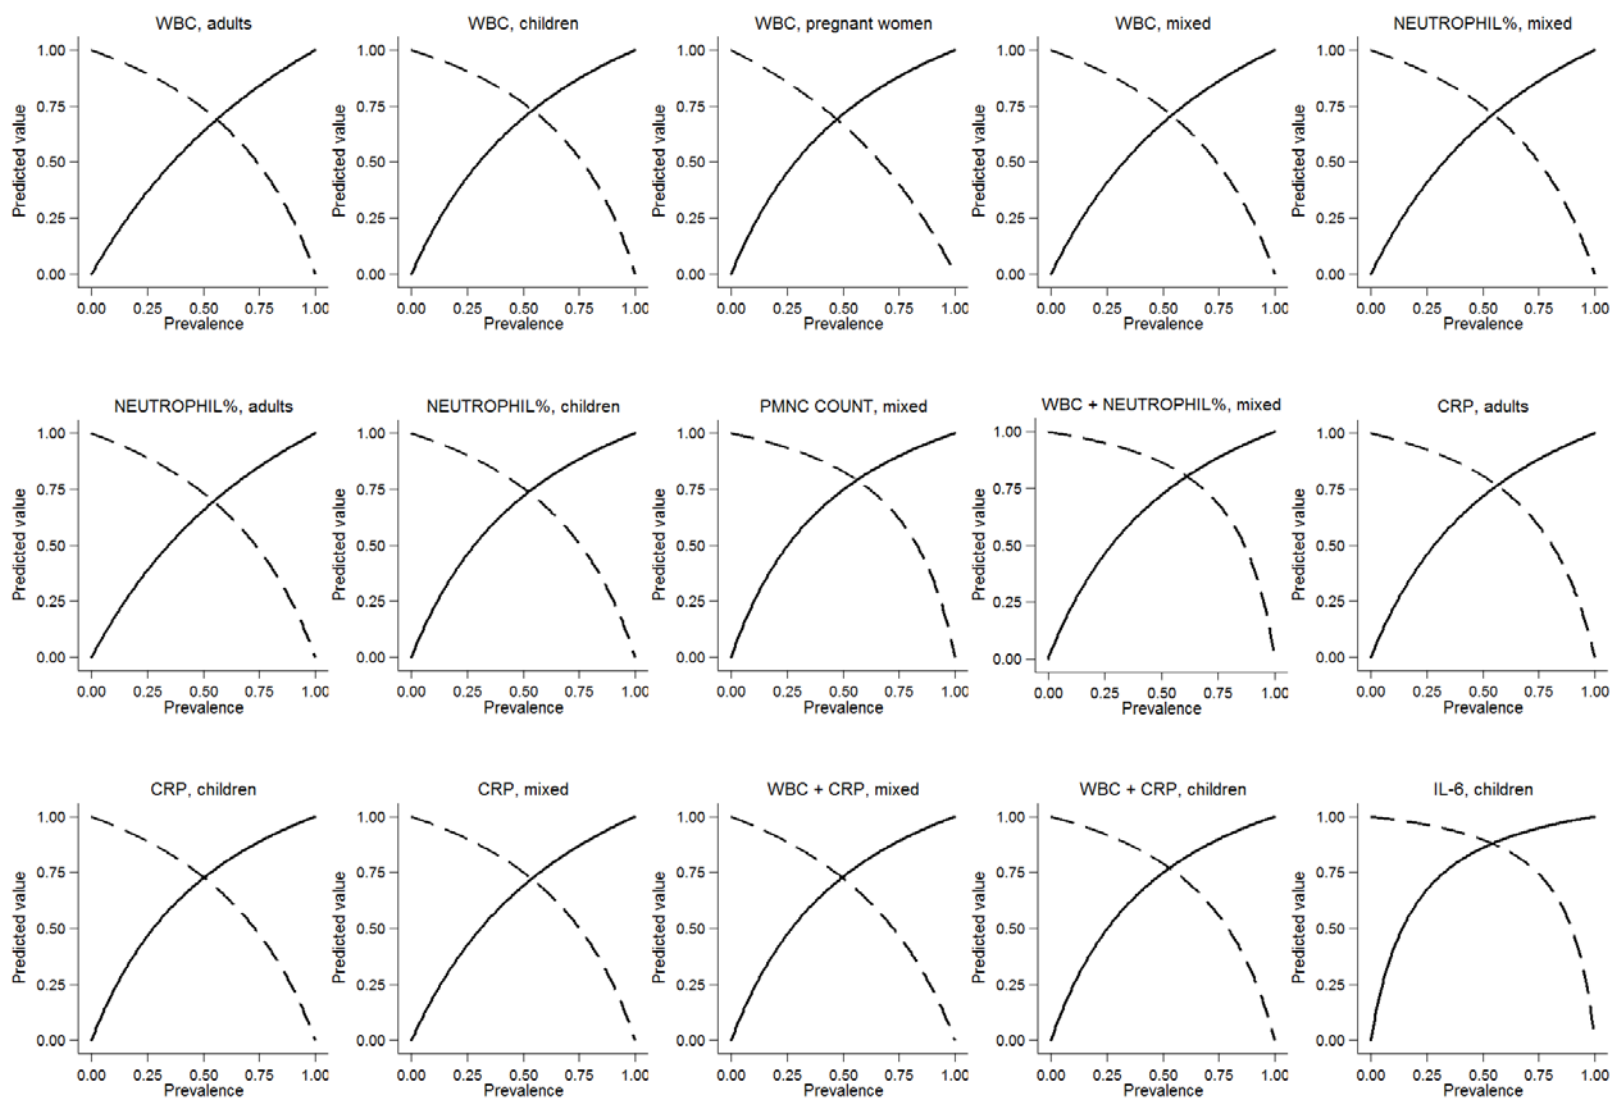

Sensitivity, specificity, and LR values are medians and 95% central credible intervals when 5 or more studies were available; medians and minimum to maximum values are reported when <5 studies were available; when a single study was available we report the estimate from that study.

**Figure 5. Scatterplot of results in the receiver operating characteristic space and summary receiver operating characteristic curves of laboratory tests for the diagnosis of acute appendicitis**

CRP = c-reactive protein; IL-6 = interleukin 6; PMNC = polymorphonuclear count; WBC = white blood cell count; sens.=sensitivity; spec.=specificity

**Figure 6. Positive predictive value and negative predictive value curves of laboratory tests for the diagnosis of acute appendicitis**

CRP = c-reactive protein; IL-6 = interleukin 6; PMNC = polymorphonuclear count; WBC = white blood cell count

## **Factors That Affect the Test Performance of Laboratory Tests**

Table 9 summarizes the results of meta-regression analyses for various factors that may affect the performance of laboratory tests for the diagnosis of acute appendicitis. The vast majority of studies did not report adequate data to assess factors that may affect test performance (i.e., based on within study comparisons); for this reason we relied on comparisons across studies (via meta-regression analyses) to identify factors that may affect test performance. Overall, no distinct pattern emerged to establish a particular factor as a modifier of test performance. For all factors examined but CrIs were wide, indicating substantial uncertainty regarding the relative test performance of tests over levels of the modifiers we examined.

## **Impact of Study Risk of Bias Items on Estimated Test Performance**

Table 10 summarizes the results of meta-regression analyses for various factors that may affect the performance of laboratory tests for the diagnosis of acute appendicitis. We only observed a single case where the 95% CrIs for a risk of bias item did not include the null value: studies of white blood cell count that had complete verification of index test results had lower specificity than studies with incomplete verification; these results were rather imprecise (i.e., CrIs were wide). More generally, these results should not be taken to mean that there is no potential for bias in studies of laboratory tests. Our analyses relied on information that was often poorly reported in the primary studies and meta-regression results were often imprecise, indicating substantial uncertainty. Because each risk of bias item was examined individually, and because different items may be correlated between them and with other study characteristics that may affect performance estimates, we do not believe that definitive conclusions about specific items can be reached.

CRP = c-reactive protein; N = number; pts. = patients; ref. std. = reference standard; WBC = white blood cell count

Sensitivity, relative sensitivity, specificity, and relative specificity values are medians and 95% central credible intervals when 5 or more studies were available; medians and minimum to maximum values are reported when <5 studies were available; when a single study was available we report the estimate from that study.

## **Test Performance of Multivariable Diagnostic Scores**

One hundred and twenty seven studies reported information on one or more multivariable diagnostic scores. The authors usually proposed two types of cut points for these scores: a low value, below which patients might be safely discharged or observed (we refer to this cut point as the “low-risk cutoff”), and a high value, above which patients could proceed to surgery without additional investigation (we refer to this cutoff as the “high-risk cutoff”). When studies reported results at multiple cut point, analyses were performed at a “low risk” and “high risk” cut points suggested by the original score developers or recommended in subsequent studies. For scores developed specifically for binary classification, we used a single cut point. The majority of multivariable diagnostic scores had been developed prior to the widespread use of diagnostic imaging with CT and US. However, more recently developed scores have been developed with the intention of identifying a low risk group in whom imaging can be omitted.

Fifty-six of the studies enrolled mixed populations; 36 enrolled exclusively adults and 31 enrolled exclusively children; two studies were conducted in women of reproductive age; no studies were conducted in pregnant women or the elderly. Table 11 summarizes the descriptive characteristics of studies assessing the test performance of multivariable diagnostic scores and Table 12 summarizes key elements related to study risk of bias.

**Table 11. Descriptive characteristics for studies evaluating score tests for the diagnosis of acute appendicitis**

Patient Population	N Studies (Median N Patients/Affected/ Unaffected)	Median % of Women	Median of Average Age (Yrs)	Community Setting	Ambulatory Setting	Surgical Cohort	Clinical Presentation Consistent With Appendicitis	Median % of Patients With Perforation
Adults	55 (201/87/67)	47.8%	30.1	0.0%	38.2%	32.7%	98.2%	11.6%

ref. std. = reference standard; yrs = year

Table 13 summarizes the variables and scoring systems used in five or more of the included studies. The most commonly used score was the Alvarado score (n=77), developed from a cohort of patients who all underwent appendectomy, and includes three items created by dichotomizing continuous predictors, white blood cell count (10 or more), neutrophil percentage (75% or more) and increased temperature ( $\geq 37.3$  Celsius). Studies often (n=11) assessed variants of the Alvarado score neutrophil percentage is not reported (or reported in a delayed fashion) by some laboratories. Thus, subsequent papers have frequently modified the original Alvarado score by omitting this element.

**Table 13. Components and scoring methods for appendicitis scores evaluated in at least five studies**

Score	Components	Scoring Rule and Item Weights	Interpretation of Results
<b>Alvarado score</b>	Migration of pain	+1	The score is obtained by summing the components using the weights. Higher values indicate higher probability of appendicitis. Maximum total score is 10. The <b>modified Alvarado</b> score omits <i>Shift to the Left</i> resulting in a total score of 9. For both scores, a low risk cutpoint of $\geq 5$ and a high risk cutpoint $\geq 7$ were evaluated.
	Anorexia/Acetone	+1	
	Nausea/Vomiting	+1	
	Tenderness in RLQ	+2	
	Rebound pain	+1	
	Elevated temperature	+1	
	Leukocytosis	+2	
	Shift to left	+1	
<b>PAS</b>	Pain with cough/percussion/hopping	+2	This score was developed for use in children. A low risk cutpoint of $\geq 6$ and a high risk cutpoint $\geq 8$ were evaluated.
	Anorexia	+1	
	Elevated temperature	+1	
	Nausea/Vomiting	+1	
	Tenderness over right iliac fossa	+2	
	Leukocytosis	+1	
	Shift to left	+1	
	Migration of pain	+1	

PAS = Pediatric Appendicitis Score

Tables 14 and 15 summarize information on the test performance of various multivariable diagnostic scores. In general, their test performance appeared to be better than that of their component clinical symptoms and signs, but still lower than that of imaging tests. Figure 7 presents study results and summary ROC curves for selected multivariable diagnostic scores. Figure 8 shows the positive and negative predictive value for selected multivariable diagnostic scores, over appendicitis prevalence.

Table 16 summarizes the results of meta-regression analyses. There was some indication that the sensitivity of the Alvarado score has been lower in more recent studies (published from 2005 onwards).

## Test Performance of Imaging Tests

Five hundred and nineteen studies, published between 1965 and 2014, provided information on the test performance of imaging tests for the diagnosis of acute appendicitis. By far the most commonly evaluated tests included CT, US, and MRI.

Table 17 presents a summary of the descriptive characteristics of the studies. Table 18 presents a summary of key items related to study risk of bias. Studies of CT and MRI were at moderate risk of bias; studies of US and other imaging tests were at moderate to high risk of bias. In general, blinding of index test and reference standard assessors were either not used or relevant information was not reported; and most studies had differential verification.

Table 19 presents a summary of key test performance results for imaging tests. CT and MRI had high sensitivity and specificity in all populations for which data were available; US had lower sensitivity and comparable specificity. Positive and negative likelihood ratios were generally higher for CT and MRI, as compared to US, but all three tests had likelihood ratios that are clinically relevant. US also had substantially higher rates of non-diagnostic exams (the median percentage of non-diagnostic scans for CT was lower than 6% for all populations examined; the median proportion was substantially higher for US). However, the reporting of information on non-diagnostic scans was inconsistent across studies, raising concerns reporting bias. Computed tomography (CT) had high sensitivity (summary estimates ranging from 0.95 to 1) and specificity (ranging from 0.91 to 0.99) in all populations of interest to this report. MRI had high sensitivity (ranging from 0.91 to 1) but appeared to have variable specificity (ranging from 0.86 to 1), mainly due to the smaller number of available studies, which focused on its use for pregnant women. In adult populations, US had lower sensitivity (0.83) and specificity (0.89) than CT (0.96, both for sensitivity and specificity) and MRI, and produced more non-diagnostic scans. In children, the specificity of US was similar to that of CT (0.92 vs. 0.91), but CT had greater sensitivity (0.89 vs. 0.96); these results were based on a large number of studies (72 for US and 32 for US). In the same patient population, MRI had a specificity of 0.99 and sensitivity of 1, but data were derived from only 3 studies. Among pregnant women, CT, MRI, and US had similar specificity (0.98, 0.98, and 0.95, respectively), but CT and MRI had higher sensitivity than US (0.95, 0.98, and 0.73, respectively).

Figure 9 presents study results and summary ROC curves for selected imaging tests. Studies of CT exhibited low heterogeneity in sensitivity and moderate heterogeneity in specificity; studies of US exhibited more heterogeneity, both for sensitivity and specificity. Studies of MRI had relatively homogeneous sensitivity and specificity, but the number of available studies was too limited to draw conclusions about consistency. Studies of other tests showed moderate heterogeneity. For all imaging tests, in most cases, summary ROC lines appeared to fit the data relatively well. Figure 10 shows the positive and negative predictive value for selected imaging tests, over appendicitis prevalence.

Sensitivity analyses using test readings from worse performing raters (see methods section for a description of details of these analyses) produced results that were similar to our main analyses (which used test readings from the rater with the highest sum of sensitivity and specificity). Sensitivity analyses for the impact of indeterminate test results produced test performance estimates that were lower than the main analyses; the deterioration of performance was more pronounced for US (as compared to CT and MRI), reflecting the higher rate of indeterminate results. The complete sensitivity analyses are presented in Appendix D.

## **Factors That Affect the Test Performance of Imaging Tests**

Table 20 summarizes the results of meta-regression analyses for various factors that may affect the performance of imaging tests for the diagnosis of acute appendicitis.

The vast majority of studies did not report adequate data to assess factors that may affect test performance (i.e., based on within study comparisons); for this reason we relied on comparisons across studies (via meta-regression analyses) to identify factors that may affect test performance. Overall, no distinct pattern emerged to establish a particular factor as a modifier of test performance. For all factors examined but CrIs were wide, indicating substantial uncertainty regarding the relative test performance of tests over levels of the modifiers we examined.

## **Impact of Study Risk of Bias Items on Estimated Test Performance**

Table 21 summarizes the results of meta-regression analyses for various factors that may affect the performance of imaging tests for the diagnosis of acute appendicitis. In some cases items related to study risk of bias appeared to be associated with worse test performance of various clinical symptoms and signs. Specifically, for CT in adult populations, differential verification and blinding of index test assessors were associated with higher specificity. For CT in children, incomplete verification was associated with higher sensitivity. For CT in mixed populations differential verification was associated with higher specificity and partial verification was associated with lower sensitivity. For US in adults, the use of prespecified positivity criteria were associated with higher sensitivity. For US in children complete verification was associated with higher sensitivity. For US in mixed populations differential verification was associated with higher sensitivity and specificity, partial verification was associated with lower sensitivity, and using a consecutive or random sample of patients was associated with higher sensitivity.

These results suggest that study conduct may have affected estimates of test performance in meta-analyses of imaging tests. However, our analyses relied on information that was often poorly reported in the primary studies and meta-regression results were often imprecise, indicating substantial uncertainty. Because each risk of bias item was examined individually, and because different items may be correlated between them and with other study characteristics that may affect performance estimates, we do not believe that definitive conclusions about specific items can be reached.

**Table 20. Meta-regression results for factors that affect the performance of imaging tests for the diagnosis of acute appendicitis**

Test	Population	Subgroup		N Studies	Sensitivity	Relative Sensitivity	Specificity	Relative Specificity

CT = computed tomography; IV = intravenous; N = number; NOS = not otherwise specified; US = ultrasound

Sensitivity, relative sensitivity, specificity, and relative specificity values are medians and 95% central credible intervals when 5 or more studies were available; medians and minimum to maximum values are reported when <5 studies were available; when a single study was available we report the estimate from that study.

CT = computed tomography; MRI = magnetic resonance imaging; N = number; pts. = patients; US = ultrasound Sensitivity, relative sensitivity, specificity, and relative specificity values are medians and 95% central credible intervals when 5 or more studies were available; medians and minimum to maximum values are reported when <5 studies were available; when a single study was available we report the estimate from that study.

## **Classifiers and Computer-Aided Diagnosis**

We also identified 52 studies of various multivariable classifiers (other than diagnostic scores). We did not extract detailed information from these studies because they generally did not report results in a way that would allow the use of the classifiers in current practice or described software that is not currently applicable. For completeness, a list of these studies is provided in Appendix E.

## **Test Performance of Diagnostic Laparoscopy**

Fifty-five studies, published between 1974 and 2014, reported information on the test performance of diagnostic laparoscopy. The sample sizes ranged from 23 to 1899, and prevalence of appendicitis ranged from 3 to 95 percent, with a median of 65 percent.

The reporting of methods and test performance outcomes in these studies was less complete than that of studies of other tests. In addition, studies had heterogeneous (and often incompletely reported) policies for the management of cases when laparoscopy did not reveal an inflamed appendix or no other pathology. Such differences can influence the estimates of test performance and for this reason we did not perform any quantitative synthesis for the test performance of diagnostic laparoscopy. It is important to note that patients included in studies of diagnostic laparoscopy (e.g., have more severe symptoms, or have atypical findings in other) are different from patients included in studies of non-invasive tests (even if the selection criteria are not clearly presented). Thus, indirect comparisons among test categories are not likely to be meaningful.

Because of the generally poor reporting, quality assessment of these studies was challenging. Most reported their criteria for a positive laparoscopic examination, but did not discuss how and when it was established. The reference standard varied across studies and populations. Generally, more than 90 percent of enrolled patients were included in the analysis and received a reference standard, but in approximately half of the studies there was differential verification.

Sixteen studies looked at laparoscopy in women of reproductive age. This was the only subgroup reported on in more than two studies. Mean and median ages ranged from 21 to 30. Prevalence ranged from 39 to 92 percent of the population (median 59%). These results are reported along with the others below.

## **Tests Positive for Appendicitis**

Generally, tests were reported as positive for appendicitis when the appendix appeared inflamed, though the precise definition varied across studies. Forty-two studies reported on this outcome. The median total positive diagnoses in those receiving diagnostic laparoscopy was 64 percent (min 23%, max 100%, 25<sup>th</sup> percentile 51%, 75<sup>th</sup> percentile 78%). The median correct diagnoses of appendicitis in those receiving diagnostic laparoscopy was 57 percent (min 16%, max 100%, 25<sup>th</sup> percentile 47%, 75<sup>th</sup> percentile 75%). The median incorrect diagnoses of appendicitis in those receiving diagnostic laparoscopy was 0 percent (min 0%, max 21%, 25<sup>th</sup> percentile 0 %, 75<sup>th</sup> percentile 6%).

In 16 studies of women of reproductive age, the median total positive diagnoses in those receiving diagnostic laparoscopy was 64 percent (min 22%, max 92%, 25<sup>th</sup> percentile 56%, 75<sup>th</sup> percentile 74%). The median correct diagnoses of appendicitis in

those receiving diagnostic laparoscopy was 57 percent (min 16%, max 92%, 25<sup>th</sup> percentile 53%, 75<sup>th</sup> percentile 68%). The median proportion of incorrect diagnoses of appendicitis in those receiving diagnostic laparoscopy was 3 percent (min 0%, max 1%, 25<sup>th</sup> percentile 0%, 75<sup>th</sup> percentile 6.5%).

## **Sensitivity and Specificity**

For the 54 studies for which they could be calculated, the median sensitivity and specificity were 100 and 89 percent, respectively. However, there was a wide range with sensitivity ranging from 37 to 100 percent (25<sup>th</sup> percentile 95%, 75<sup>th</sup> percentile 100%) and specificity ranging from 0 to 100 percent (25<sup>th</sup> percentile 73%, 75<sup>th</sup> percentile 100%). This variability likely reflects the heterogeneous populations evaluated in these studies (which often do not describe the details of patient selection).

In the 16 studies that reported on women of reproductive age, the median sensitivity was 100 percent (min 90%, max 100%, 25<sup>th</sup> percentile 100%, 75<sup>th</sup> percentile 100%), and the median specificity was 89 percent (min 73%, max 100%, 25<sup>th</sup> percentile 79%, 75<sup>th</sup> percentile 100%).

## **Tests Positive for Other Pathology**

Forty-one studies reported some information on other pathology diagnosed at laparoscopy. The median proportion of patients with non-appendiceal pathology identified was 22 percent (min 0%, max 71%, 25<sup>th</sup> percentile 11.5%, 75<sup>th</sup> percentile 34%). Only six small studies reported that other pathology was found when appendicitis was also present. The median was 5 percent (min 0.5%, max 20%, 25<sup>th</sup> percentile 2%, 75<sup>th</sup> percentile 13%). In nine studies of women of reproductive age, the median proportion of patients with non-appendiceal pathology identified was 23 percent (min 6%, max 40%, 25<sup>th</sup> percentile 18%, 75<sup>th</sup> percentile 26%), none were in patients who also had appendicitis.

## **Appendix not Visualized (Indeterminate Findings)**

Twenty-six studies reported at least partially on inability to visualize the appendix. The median was 6 percent (min 1%, max 51%, 25<sup>th</sup> percentile 3%, 75<sup>th</sup> percentile 10%). These were slightly more likely to be negative than positive. Median proportions were 2.6 percent and 1 percent, respectively. The range for patients without appendicitis was 0 to 51 percent (25<sup>th</sup> percentile 1%, 75<sup>th</sup> percentile 6%). The range for those with appendicitis was 0 to 30 percent (25<sup>th</sup> percentile 0%, 75<sup>th</sup> percentile 7%). In ten studies of women of reproductive age, the median was 5 percent (min 3%, max 17%, 25<sup>th</sup> percentile 4.5%, 75<sup>th</sup> percentile 8%). In this population, there was little difference between those with and without appendicitis. The median proportion with appendicitis was 3.5 percent (min 0%, max 10%, 25<sup>th</sup> percentile 0%, 75<sup>th</sup> percentile 6%). The median proportion without appendicitis was 3 percent (min 1%, max 19%, 25<sup>th</sup> percentile 2%, 75<sup>th</sup> percentile 6%).

## **No Cause Found**

Thirty-five studies gave information on cases in which the appendix appeared normal and no other pathology was found. The median percentage of patients who had diagnostic laparoscopy with no pathology found was 11 percent (min 5%, max 26%, 25<sup>th</sup> percentile

8%, 75<sup>th</sup> percentile 18%). Again, these were more likely to be patient without appendicitis. The median was 4 percent with appendicitis and 9 percent without. The range for patients without appendicitis was 2 to 29 percent (25<sup>th</sup> percentile 5%, 75<sup>th</sup> percentile 14%). The range for those with appendicitis was 1 to 9 percent (25<sup>th</sup> percentile 1%, 75<sup>th</sup> percentile 5%), but these were less likely to be reported (9 studies).

In ten studies of women of reproductive age, the percentage of patients who had diagnostic laparoscopy with no pathology found was only reported for those without appendicitis. The median was 13 percent (min 2%, max 29%, 25<sup>th</sup> percentile 8%, 75<sup>th</sup> percentile 19%).

## **Risk of Bias in Studies of Diagnostic Laparoscopy**

Most studies enrolled patients using a consecutive or random sampling method, one explicitly stated that the authors used a convenience sample, and the sampling method was unclear in 25. Thirty-one studies avoided inappropriate exclusions, but this could not be assessed in 24.

In 46 studies it was clear that the index test results were interpreted without knowledge of the results of the reference standard, but this was unclear in nine. Only two studies reported that the criterion for a positive diagnostic laparoscopy was prespecified, 52 were unclear, and one clearly did not use a prespecified threshold. Only four studies clearly stated that the reference standard results were interpreted without knowledge of the results of the index test; 51 were unclear.

The reference standard varied widely among studies from all receiving pathologic diagnosis to some receiving pathologic diagnosis and others receiving some sort of followup. In 40 studies the reference standard was deemed likely to correctly classify the target condition, one clearly was not, and in 14 studies it was unclear. Fifteen studies reported an appropriate interval between index tests and reference standard, six clearly did not have an appropriate interval, 13 were unclear, and in 21 this was not applicable because all patients had verification by pathology. Fifty studies had all patients receiving a reference standard, one had partial verification, and four were unclear. Nearly all studies (53) included all patients in the analysis, one did not, and the other as unclear. However, because of the fact that the reference standard varied based on index test in some studies, 24 studies had all patients receive the same reference standard, 28 had patients receiving different reference standards, and three were unclear.

## **Comparative Assessments of Test Performance**

Information on comparative test performance was sparse. The majority of included studies assessed a single index test; thus allowing only *indirect* comparisons among tests of interest (i.e., comparisons based on the test specific estimates presented in the preceding sections of this chapter). Because studies differ in many ways, including the patient populations they sample, the selection criteria they use, and the specific implementation of the various test strategies, cross-study comparisons provide only weak evidence regarding comparative test performance (because any differences in test performance may be attributable to cross-study differences in factors other than specific test assessed). For this reason, our assessment of comparative test performance relied primarily on randomized and non-randomized *direct comparisons* (i.e., within-study) of tests.

## **Randomized Comparisons of Alternative Tests**

Thirty-six RCTs reported information on comparative test performance; all studies had a parallel arm design (i.e., none used a paired design). Overall, on the basis of items from the Cochrane risk of bias tool, RCTs were deemed to be at moderate risk of bias. Details on the risk of bias of individual studies are presented in the next chapter of this report (Key Question 2) because the studies assessed outcomes beyond test performance. Results on selected test performance comparison are summarized in Tables 22 to 25; additional extracted data are presented in Appendix F. Data were sparse because each possible contrast (between alternative test strategies or versions of a test strategy) were typically examined by one or two trials and because not all trials reported information on the same outcomes. Studies were small, produced imprecise results, therefore we could not make any definitive conclusions about the relative test performance of the strategies compared based on RCTs.

## **Nonrandomized Comparisons of Alternative Tests**

Non-randomized studies of test performance were not synthesized with RCTs because the latter were deemed to be at substantial risk of bias (confounding and selection bias) and often provided inadequate information to understand their design (see below).

## **Nonrandomized Comparisons of CT and US**

Fifty-three studies reported results in cohorts using both CT and US as index tests, potentially permitting direct (within-study) nonrandomized comparisons of these modalities. Ten studies investigated CT as a replacement for US, 13 investigated US as a triage test for CT, and 30 studies were unclear about the actual role of testing that was being evaluated (studies often used convenience samples of patients that were selected using criteria that were often not reported; results from these studies are presented in Figure 11 for completeness; though these studies suggested that CT generally has better test performance than US, the strength of this evidence was itself weakened by the lack of information on the exact study design).

Nine of the studies had a paired design (both tests applied to the same patient group) and 44 had a parallel group design (separate groups of patients received each test). Figure 11 presents diagnostic ORs from these studies (higher values indicate better performance) and relative diagnostic ORs (comparing CT vs. US; values higher than 1 indicate that CT had better test performance than US). In general, CT had better test performance than US, when used as a replacement test. In the triage context, CT had high test performance (diagnostic odds ratios higher than 10 and often higher than 100) in patient populations selected on the basis of US results (typically, nondiagnostic US findings, or negative findings in the presence of symptoms suggestive of appendicitis).

## **Nonrandomized Comparisons of MRI and US**

Eight studies reported results in cohorts using both MRI and US as index tests, potentially permitting direct (within-study) nonrandomized comparisons of these modalities. Four studies investigated MRI as a replacement for US, one investigated US as a triage test for MRI, and three studies were unclear about the actual role of testing that was being evaluated (these studies tended to use convenience samples of patients that were selected for a specific test using criteria that were often not reported; this studies

were included in the review for completeness; however, the strength of the evidence they provide is weakened by the lack of information on the exact study design). Four of the studies had a paired design (both tests applied to the same patient group) and four had a parallel group design (separate groups of patients received each test). Studies investigating MRI as a replacement test suggested that MRI, when used as a replacement test for US has greater test performance, however the available studies are few and have produced rather imprecise results.

**Figure 11. Test performance results in studies evaluating both CT and US as index tests**

CT = computed tomography; OR = odds ratio; PMID = PubMed identification number; US = ultrasound

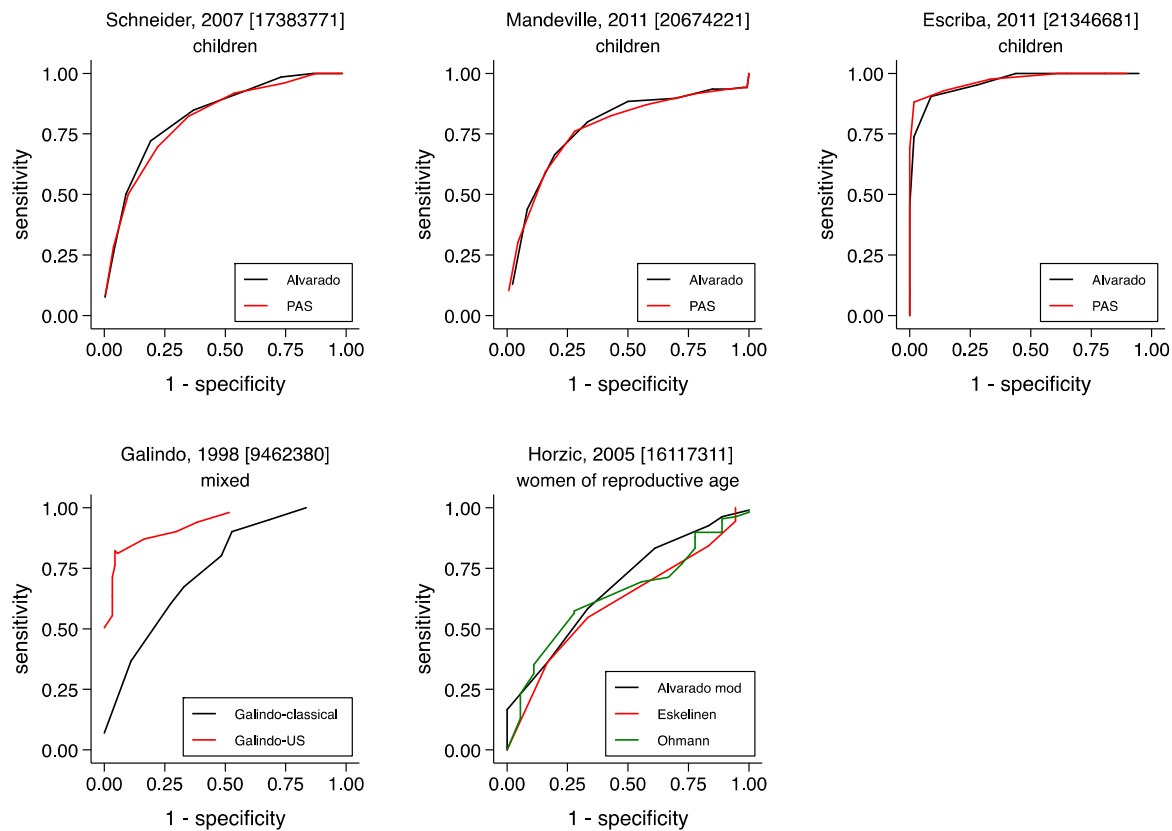

Forest plot of results from studies assessing CT and US as index tests. Studies are ordered by the magnitude of the difference between the diagnostic OR of CT and US and are labeled by their first author, year of publication, and PMID. Both panels: top group of studies = studies evaluating US as a triage test for CT; middle group of studies = studies evaluating CT as a replacement test for US, bottom = studies where the role of testing evaluated was unclear. Capital letters in the y-axis label denote the population enrolled: A = adults; C = children; M = mixed; R = women of reproductive age; P = pregnant women. Left panel: diagnostic ORs for CT (black circles) and US (white circles), with corresponding confidence intervals; greater values denote better test performance. Right panel relative ORs comparing the test performance of CT and US (relative ORs are not shown for studies evaluating US as a triage test); values > 1 denote better test performance by CT (as compared to US). X-axis scale is logarithmic on both panels. For paired designs we have assumed that the correlation between the diagnostic ORs of the tests being compared is 0 (this correlation was not reported in the primary studies). This is a conservative assumption (i.e., it leads to wider confidence intervals) because the correlation is generally expected to be positive, and accounting for it would result in narrower confidence intervals compared to those depicted in the graph.

## Nonrandomized Comparisons of Diagnostic Scores

Eight studies reported direct comparisons among alternative diagnostic scores for appendicitis.<sup>68-70 25,71-74</sup> Three studies included children, one included women of reproductive age, and four included mixed populations. Five of the studies reported results on three or more score cutoffs, and their results are shown in Figure 12. Across all eight studies, differences in test performance between scores were small; this was particularly true for the comparison of the Alvarado and PAS scores applied to children with suspected acute appendicitis. The one exception was a study that compared a multivariable diagnostic score based on clinical symptoms and signs versus a score combining the same clinical variables with the addition of US: incorporation of US information improved test performance substantially, with respect to both sensitivity and specificity.<sup>74</sup>

**Figure 12. Receiver operating characteristic curves from studies comparing two or more appendicitis diagnostic scores**

7

Mod. = modified; PAS = pediatric appendicitis score; US = ultrasound

Each panel represents a within-study comparison among two or more diagnostic scores. Study results were used to reconstruct the empirical receiver operating characteristic curves. In the study by Galindo et al. the empirical ROC curve appears to not be monotonic; we have verified our data extraction against the paper and we believe that this may be the results of a reporting or typographical error in the publication.

Key Question 2: What is the comparative effectiveness of alternative diagnostic tests, alone or in combination, for patients with RLQ pain and suspected acute appendicitis?

## **Included Studies With Information on the Comparative Effectiveness of Alternative Test Strategies**

Fifty-four studies provided information on the comparative effectiveness of alternative test strategies (36 RCTs and 18 NRCSs) in patients with RLQ pain. We only considered RCTs and NRCSs for the assessment of comparative effectiveness. Indirect (cross-study) comparisons for such outcomes are likely to be confounded by factors that differ across studies. We only considered NRCSs that enrolled at least 1000 patients because comparative effectiveness outcomes are relatively rare; as such, a large sample is needed to obtain reliable estimates of effect – especially if statistical adjustments for possible confounders are to be performed. Detailed information from the included RCTs and NRCS is presented in Appendix F; key study characteristics and findings are summarized below. Because pregnant women are underrepresented in RCTs and NRCSs of alternative test strategies, we collected information on fetal and maternal outcomes from non-comparative cohort studies that enrolled at least 10 patients. Many of the included studies were small and may have produced unstable estimates of event rates, as well as treatment effects. Furthermore, selection criteria differed substantially among trials (as would be expected by the very different nature of the compared test modalities), rendering indirect comparisons uninformative.

## **Computed Tomography Versus Routine Management or Clinical Assessment**

Seven RCTs<sup>75-83</sup> (described in 9 publications) with a total of 1177 participants compared the use of CT imaging to routine management in the diagnosis of appendicitis and reported comparative effectiveness outcomes (Table 26). Four studies reported details of adequate random sequence generation,<sup>76,78-80,82</sup> and two studies described adequate allocation concealment procedures.<sup>76</sup> Two studies described blinding of outcome assessors to group assignment<sup>76,82</sup> Loss to followup was greater than 10% in three studies.<sup>75,76,78</sup>

Hong et al. (2003) reported no significant difference between clinical observation alone versus clinical observation and abdominopelvic CT in terms of perforations ( $p = 0.4$ ) among adults evaluated for possible acute appendicitis. In the clinical observation group, there were four perforations in 68 patients, while in the clinical observation plus CT group, there were seven perforations in 78 patients. The mean length of hospital stay was also not significant ( $p = 0.55$ ) at  $2.4 (\pm 3.2)$  days in the clinical observation group and  $2.2 (\pm 2.2)$  days in the clinical observation and CT group. However, the mean time from presentation to surgery was significantly less in the clinical observation group ( $P < 0.01$ ), at 10.6 hours as compared to 18.7 hours in the clinical observation and CT group.<sup>75</sup>

Lopez et al. (2007) also compared clinical observation alone versus clinical observation and abdominopelvic CT among women of childbearing age with possible acute appendicitis. There were no perforations in either group, and both groups reported a median days of hospital stay at 1 day (range: clinical observation alone 0 to 7 days, clinical observation plus CT 0 to 6 days;  $p = 0.22$ ).<sup>78</sup>

Walker et al. (2000) reported a higher negative appendectomy rate in the standard care group (7 of 36), as compared to the group that had a limited CT scan versus colorectal contrast (2 of 38;  $p = 0.08$ ), among adult patients receiving surgical consultation for appendicitis.<sup>83</sup>

Lee et al. (2007) compared selective versus mandatory CT imaging in adult patients presenting with acute right lower quadrant pain and suspected acute appendicitis. They reported a difference of 8.2 percent (95% CI, -8.0, 24.4) for perforations, with a rate of 18.4 percent (7 of 38) in the selective imaging group and 10.3% (4 of 39) in the mandatory imaging group. The difference in negative appendectomy rates was 11.3 percent (95% CI, -3.5, 26.3), with a rate of 13.9 percent (6 of 43) in the selective imaging group and 2.6 percent (1 of 39 patients) in the mandatory imaging group. The mandatory CT group had 0.9 hour longer mean time from ED triage to surgery, 10.9 ( $\pm 6.9$ ) hours as compared to 10 ( $\pm 7$ ) hours in the selective imaging group.<sup>76</sup>

Lehtimäki et al. (2013) compared selective and mandatory CT imaging among patients presenting to a surgical emergency department with acute abdominal pain lasting more than 2 hours and less than 7 days. There was one negative appendectomy in 111 patients in the selective group, and one negative appendectomy in 143 patients in the mandatory group ( $p > 0.99$ ). The mean length of hospital stay was significantly shorter ( $p = .01$ ) in the selective group (2.5 days, min 0, max 21) as compared to the mandatory group (3.7 days, min 0, max 32).<sup>77</sup>

Three publications presenting results from the study by Ng et al. (original publication 2002; additional information presented in 2007 and 2010) reported outcomes for the same cohort of adult patients with acute abdominopelvic pain admitted under the care of the surgical team in a single academic hospital and randomized to either current standard practice versus early CT (within 24 hours). Both groups had a median five days' hospital stay ( $p = 0.2$ ), but there were significantly more deaths in the standard care group (7 of 63) than in the early CT group (0 of 55;  $p = 0.014$ ).<sup>79-81</sup> Of note, mortality was not an a priori endpoint for this study. Two of these studies also reported information on the impact of testing on diagnostic confidence. Both reported that diagnostic confidence increased between admission and 24 hours after admission in both groups, but that the increase was not significantly greater in the CT group (25.2%) than in the standard care group (24.9%;  $p = 0.098$ ).<sup>79,81</sup>

Sala et al. (2009) randomized patients presenting to the "on-call" surgeons with acute "nonspecific" abdominal pain to current standard practice versus CT within one hour. This study also reported length of stay and mortality. The median length of hospital stay for the standard care group was 5.3 days (25<sup>th</sup> percentile 2 days, 75<sup>th</sup> percentile 9.5 days), and the median for the early CT group was 4.2 days (25<sup>th</sup> percentile 1.1 days, 75<sup>th</sup> percentile 7.6 days). There were 11 deaths within 6 months in the standard care group, as compared to six of 99 in the early CT group ( $p = 0.31$ ).<sup>82</sup>

Seven large NRCS with a total of 149,422 participants compared the use of CT imaging to routine management in the diagnosis of appendicitis and reported comparative effectiveness outcomes.<sup>84-90</sup> One study was prospective, with more than 90 percent follow-up;<sup>86</sup> the others were retrospective.

McGory et al. reported a non-significant difference in negative appendectomy rate in 4731 patients with a CT scan (8%) versus 70721 patients who did not have a CT scan (9.4%;  $p = 0.36$ ). However, there were statistically significantly more cases of appendicitis with abscess in the CT group (18.6%) compared to the non-CT group (9.3%). ( $p < 0.001$ ), and mean and median length of stay was statistically significantly longer in the CT group (mean  $5.46 \pm 5.21$  days;

median 4, min 0, max 83) than the non-CT group (mean  $3.28 \pm 4.04$  days; median 2, min 0, max 289) ( $p < 0.001$ ).<sup>84</sup>

Raja et al. and Wagner et al. found significant differences in the negative appendectomy rate between patients with and without CT before surgery. Raja et al. reported a negative appendectomy rate of 1.7 percent in a group of 637 patients, 97.5 percent of whom had a CT scan and 23 percent in a group of 971 patients only one percent of whom had a CT scan ( $p < 0.001$ ).<sup>86</sup> Wagner et al. also found a lower negative appendectomy rate in 1070 patients who had CT scan (7.2%) compared to 129 patients who did not (14%;  $p = 0.007$ ).<sup>89</sup> Bachur et. al reported on 55,227 children based on age. For children under five, they found that CT reduced the negative appendectomy rate significantly ( $p < 0.001$ ; boys: OR 0.18; 95% CI 0.12 to 0.28; girls: OR 0.11; 95% CI 0.07 to 0.18) from approximately 22 percent without CT to approximately 5 percent with CT, but for children between five and ten (boys:  $p = 0.123$ ; OR 0.68; 95% CI 0.42 to 1.11; girls:  $p = 0.236$ ; OR 0.78; 95% CI 0.51 to 1.18) and children over ten (boys:  $p = 0.556$ ; OR 1.10; 95%CI 0.79 to 1.57; girls:  $p = 0.598$ ; OR 1.07; 95%CI 0.83 to 1.38) the reduction was not significant.<sup>90</sup> Petrosyan et al. reported similar overall negative appendectomy rates between the groups (with CT 6%, 31 of 546; without CT 6%; 23 of 383), but in to patients with an Alvarado scores of 5 to 7, the CT group had a lower negative appendectomy rate (3.3%; 12 of 357) than the non-CT group (6.2%; 20 of 321) (mean difference 2.9%, 95% CI: 0.3% to 6%).<sup>85</sup> Tsao et al. reported a lower perforated appendix rate in children who had a CT scan (24.6%, 159 of 646) than those who did not (33.8%, 117 of 346).<sup>88</sup>

Shalligram et al. reported significant differences between 11,340 men (18 to 55 years old) who had a CT scan as part of their diagnostic workup and 1888 who did not. Mean length of stay was statistically significantly longer for those with CT scan ( $1.66 \pm 1.63$  days) than those who did not ( $1.37 \pm 0.6$  days) ( $p < 0.001$ ). However, readmission within 30 days, morbidity, and ICU admission were lower in the CT group. Readmission within 30 days was 1.8 percent in the CT group compared to 5.13% in the non-CT group ( $p < 0.001$ ). Morbidity was 0.86 percent in the CT group, compared to 2.2 percent in the non-CT group ( $p < 0.001$ ). The rate of ICU admissions was also lower in the CT group (1.38%) compared to the non-CT group (1.8%), but this was not significant ( $p = 0.19$ ).

**Table 26. Randomized comparisons of CT versus routine management with respect to clinical outcomes and resource utilization**

Comparison	Outcome	Author, Year [PMID]	Outcome Rate or Mean in Group 1	Outcome Rate or Mean in Group 2	Between-Group Difference*
CT vs. routine management	Deaths	Ng, 2002 [12480851]	0/57 (0.0%)	7/63 (11.1%)	-0.11 (-0.19 to -0.03); p = 0.008

CT=computed tomography

\*Risk difference for binary outcomes; mean difference for continuous outcomes. For continuous outcomes, p-values are missing when studies did not report adequate data to calculate them.

## Alternative Types of Computed Tomography

Four RCTs,<sup>91-94</sup> with a total of 1,441 participants, compared different types of CT imaging for the diagnosis of appendicitis and reported comparative effectiveness outcomes (Table 27). One study reported details of random sequence generation, adequate allocation concealment procedures, and blinding of outcome assessors to group assignment.<sup>93</sup> All studies had loss to follow-up of less than 10 percent. Three of these studies looked at differing contrast regimens for CT. Mittal et al. (2004) compared CT scans with rectal contrast only versus scans using oral, rectal, and intravenous contrast among patients with an “uncertain” diagnosis of appendicitis aged 6 years of age or older. They reported similar negative appendectomy rates in the two groups, 7.7 percent (3 of 39) in the rectal contrast group and 8 percent (4 of 48; p > 0.99) in the triple contrast group. The perforation rate was lower in the rectal contrast group (3%, 1 of 36) than in the triple contrast group (30%, 13 of 44; p = 0.002); one patient in each group died of sepsis due to perforated appendicitis (p > 0.99). However, the mean time from emergency department presentation to operation was lower in the triple contrast group (8.3 hours) than the rectal contrast group (12.2 hours).<sup>94</sup> Hersko et al. (2007), in a randomized study of a mixed patient population (16 to 83 years of age) with suspected acute appendicitis found that with no contrast, the negative appendectomy rate of CT was 25 percent (7 of 28), while with intravenous and oral contrast it was lower at 10 percent (5 of 48; p = 0.112 vs. no contrast) and with rectal contrast even lower at 7 percent (3 of 42; p = 0.08 vs. no contrast; omnibus p = 0.07 across all 3 groups).<sup>91</sup> Kepner et al. (2012) reported a shorter mean time from emergency department

presentation to disposition in the group with intravenous contrast enhanced CT alone (6:41; 25<sup>th</sup> percentile 5:03, 75<sup>th</sup> percentile 8:49) as compared to the group that had both oral and intravenous contrast (8:12; 25<sup>th</sup> percentile 6:40, 75<sup>th</sup> percentile 9:44).

Kim et al. randomized patients with suspected acute appendicitis (15 to 44 years of age) to low-dose versus standard-dose CT and examined perforation and negative appendectomy rates, median time from CT to appendectomy, and median number of days of hospital stay. Only median time from CT to appendectomy showed a statistically significant difference ( $p = 0.02$ ) with standard dose CT shorter (5.6 hours, 25<sup>th</sup> percentile 3.4, 75<sup>th</sup> percentile 9.2) than low-dose CT (7.1 hours, 25<sup>th</sup> percentile 4.3, 75<sup>th</sup> percentile 11.7). Median length of hospital stay was not significantly shorter ( $p = 0.54$ ) in the standard dose group (3.2 days; 25<sup>th</sup> percentile 2.5, 75<sup>th</sup> percentile 4.1) than in the low-dose group (3.4 days; 25<sup>th</sup> percentile 2.7, 75<sup>th</sup> percentile 4.1). The standard dose CT group had a perforation rate of 23.3 percent (42 of 180) and the low-dose CT group had a rate of 26.5 percent (44 of 166), but this difference was not statistically significant ( $p = 0.46$ ). The negative appendectomy rate was also similar between the two groups (6 of 186, 3.2% standard-dose CT; 6 of 172, 3.5% low-dose CT;  $p > 0.99$ ).<sup>93</sup>

**Table 27. Randomized comparisons of alternative types of CT with respect to clinical outcomes and resource utilization**

Comparison	Outcome	Author, Year [PMID]	Outcome Rate or Mean in Group 1	Outcome Rate or Mean in Group 2	Between-Group Difference*
IV and oral contrast-enhanced CT vs. Nonenhanced CT	Negative appendectomy	Hershko, 2007 [17566826]	5/84 (6.0%)	7/56 (12.5%)	-0.15 (-0.33 to 0.04); p = 0.117

CT=computed tomography; IV=intravenous

\*Risk difference for binary outcomes; mean difference for continuous outcomes. For continuous outcomes, p-values are missing when studies did not report adequate data to calculate them.

One NRCS<sup>95</sup> of 3764 patients examined patients receiving abdominopelvic CT during a 12 month period to compare non-oral contrast examination (2668 patients) versus traditional CT (with IV and oral contrast; 1096 patients). The authors found that the median turn-around time from test order to complete examination was 1.82 hours versus 2.36 hours ( $p < 0.001$ ); the median turn-around time from order to final interpretation was 2.9 and 3.5 hours ( $p < 0.001$ ); and the overall emergency department length of stay was 7.46 hours versus 8.18 hours ( $p = 0.003$ ), for the non-oral contrast group versus the traditional CT group, respectively.

## Computed Tomography Versus US

Two RCTs (reported in 3 publications<sup>96-98</sup>) with a total of 689 participants compared CT imaging to US for the diagnosis of appendicitis and reported comparative effectiveness outcomes (Table 28). Neither trial reported details of random sequence generation, adequate allocation concealment procedures, or blinding of outcome assessors to group assignment. One trial followed less than 90% of participants for appendicitis outcomes<sup>96</sup> and the second trial restricted its examination of changes in diagnostic decision-making to those participants who had received both initial and final diagnoses from physicians with similar levels of expertise (209 of 600; 35% of enrolled participants).<sup>98</sup>

These studies reported outcomes for both groups for negative appendectomy rates. Horton et al. (2000) reported the same rate for both the US and CT groups (6%; 4 of 70) among patients 18 to 65 years old who presented to an emergency department with a diagnosis of possible appendicitis but had an atypical presentation after initial evaluation.<sup>96</sup> Kaiser et al. reported an overall negative appendectomy rate of 3.7 percent (9 of 244), of which four were in the US only group and five were in the US plus CT group, in a RCT of children with clinically suspected acute appendicitis admitted to the emergency department of a single academic hospital.<sup>97</sup> Kaiser et al. (2004) also reported on the impact of testing on change in management outcomes. Because the difference in impact on surgeon decisionmaking between the groups was not significant ( $z = 0.89$ ), the groups were analyzed together. In total 347 of 600 children had their management changed after imaging, including 11 unnecessary operations possibly avoided, and 28 missed appendicitis avoided. In 18 cases, the imaging was false negative, but 17 of these children had appendectomy based on clinical diagnosis.<sup>98</sup>

Three NRCS<sup>30,99,100</sup> with a total of more than 11,419 participants compared CT imaging to US for the diagnosis of appendicitis and reported comparative effectiveness outcomes. Only two reported on other outcomes. The SCOAP Collaborative reported a significantly higher negative appendectomy rate in the group that had US (10.4%) compared to the group that had CT (4.1%) ( $p < 0.001$ ).<sup>30</sup> Raval et al. reported a significantly lower negative appendectomy rate in children who had only CT scans (3.6%) compared to those who had only US (6.5%) or those who had US and CT (6.6%) ( $p < 0.001$  for CT vs. US and for CT vs. US and CT). The perforation rate was significantly lower in children who had US only (29.8%) than those who had CT only (31.8%) or US and CT (36.3%) ( $p = 0.004$  for US vs. CT and US vs. US and CT). Time from admission to surgery was also significantly longer in children who had US and CT (15.4 hours) compared to US only (7.4 hours) or CT only (9.6 hours) ( $p < 0.01$  for US and CT vs. CT and US and CT vs. US), although it was not stated whether these were mean or median times.<sup>99</sup>

**Table 28. Randomized comparisons of CT versus US with respect to clinical outcomes and resource utilization**

Comparison	Author, Year [PMID]	Outcome	Outcome Rate or Mean in Group 1	Outcome Rate or Mean in Group 2	Between-Group Difference*
CT + US vs. US	Kaiser, 2002 [12034928]	Negative appendectomy	5/317 (1.6%)	4/283 (1.4%)	(-0.02 to 0.02); p = 0.867
CT vs. US	Horton, 2000 [10930484]	Negative appendectomy	4/70 (5.7%)	4/70 (5.7%)	(-0.08 to 0.08); p = 1.000

## US Versus Routine Management or Clinical Assessment

Two RCTs<sup>101-105</sup> with a total of 1102 participants compared the use of US to routine management in the diagnosis of appendicitis and reported comparative effectiveness outcomes (Table 29). One trial described random sequence generation by coin toss and did not report adequate allocation concealment procedures<sup>101</sup> and the second trial did not describe random sequence generation or adequate allocation concealment procedures.<sup>102-105</sup> Both trials followed more than 90% of participants for some outcomes, but fewer than 90% of participants for other outcomes.

Douglas et al. (2000) compared US and clinical assessment in 302 patients older than 6 years old, referred to the surgical service of a single academic hospital with suspected appendicitis. The only significant difference between the groups was for time to therapeutic operation (p = 0.016). The mean time to operation was shorter in the US group (7 hours; 95% CI: 5.9 to 8.1) than in the clinical assessment group (10.2 hours; 95% CI: 7.9 to 13). Duration of hospital stay was not significantly different between the groups (p = 0.99). The mean length of stay was similar in the two groups (53.4 hours, 95% CI: 47 to 60 in the US group; 54.5 hours; 95% CI: 46 to 63 in the clinical assessment group). The perforation rate was similar between the two groups (14 of 160, 8.8% with US; 10 of 142, 7% with clinical assessment; p = 0.58). Both groups had a single readmission for complications. In the US group, one patient was readmitted for drainage of an abscess, while in the clinical assessment group, one patient was readmitted for an early small bowel obstruction.<sup>101</sup>

Lindelius et al. compared routine management with routine management plus US. They reported a non-significant difference for mean length of hospital stay (p = 0.964). The US group had a slightly lower mean length of stay ( $4.3 \pm 5.7$  days) than routine management ( $5.4 \pm 5.7$  days). The US group also had a not statistically significant (p = 0.733) lower number of total hospital days over 2 years followup (mean  $6 \pm 26.3$  days; median 0, min 0, max 462 days) than routine management (mean  $8.7 \pm 35.6$  days; median 0, min 0, max 470 days). Two patients in the US group died within 7 days and a third died within 6 weeks. No patients in the routine management group died.<sup>103,104</sup> They also reported that US helped in making the diagnosis in 49.5 percent of patients and was considered misleading in 10.2 percent.<sup>105</sup>

Two NRCS<sup>90,106</sup> with a total of 57,553 participants compared US to no imaging for the diagnosis of appendicitis and reported comparative effectiveness outcomes. Even-Bendahan et al. reported a 6.5 percent negative appendectomy rate in the 1069 children who had US if they were equivocal followed by CT as needed and 13.2 percent in those who had no diagnostic imaging.<sup>106</sup> Bachur et al. reported that for boys under five, US increased the negative appendectomy rate significantly (p < 0.008; OR 2.07; 95% CI 1.21 to 3.54), but for girls under

five ( $p < 0.13$ ; OR 1.54; 95% CI 0.88 to 2.68) and all children between five and ten (boys:  $p = 0.61$ ; OR 0.87; 95% CI 0.52 to 1.47; girls:  $p = 0.636$ ; OR 0.87; 95% CI 0.49 to 1.55) and children over ten (boys:  $p = 0.122$ ; OR 0.56; 95% CI 0.27 to 1.17; girls:  $p = 0.897$ ; OR 1.03; 95% CI 0.64 to 1.67) US resulted in a nonsignificantly lower negative appendectomy rate.<sup>90</sup>

**Table 29. Randomized comparisons of US versus no imaging with respect to clinical outcomes and resource utilization**

Comparison	Author, Year [PMID]	Outcome	Outcome Rate or Mean in Group 1	Outcome Rate or Mean in Group 2	Between-Group Difference*
Routine management and US vs. Routine management alone	Lindelius, 2009 [19625549]	Length of Stay	4.30 days (2.40)	5.40 days (5.70)	-1.10 days (-1.98 to -0.22); $p = 0.014$
US informed by Alvarado score vs. clinical assessment and management	Douglas, 2000 [11030676]	Duration of hospitalization	53.40 hours	54.50 hours	-1.10 hours
		Duration of hospitalization	45.00 hours	40.50 hours	4.50 hours
		Perforations	14/160 (8.8%)	10/142 (7.0%)	0.02 (-0.04 to 0.08); $p = 0.582$
		Time to Surgery	7.00 hours	10.20 hours	-3.20 hours (total population)
		Time to Surgery	7.00 hours	13.10 hours	-6.10 hours (children)

US=ultrasound

\*Risk difference for binary outcomes; mean difference for continuous outcomes. For continuous outcomes, p-values are missing when studies did not report adequate data to calculate them.

## Any Imaging Versus No Imaging

Two NRCS<sup>30,90</sup> with an approximate total of 74,554 participants compared US, CT, and/or MRI to no imaging for the diagnosis of appendicitis and reported comparative effectiveness outcomes. The SCOAP Collaborative reported a significantly lower negative appendectomy rate in the group that had CT, US, or MRI (4.5%) compared to the group that had no imaging (15.4%;  $p < 0.001$ ). Perforation rates were slightly lower in the CT, US, or MRI group (15.8%) compared to the non-imaging group (15.6%), but this difference was not significant ( $p = 0.16$ ).<sup>30</sup> Bachur et. al reported that for children under five, US or CT decreased the negative appendectomy rate significantly for girls under five ( $p = 0.011$ ; OR = 0.24; 95% CI 0.08 to 0.72), but not significantly for boys under five ( $p < 0.125$ ; OR = 0.56; 95% CI 0.27 to 1.17). For children between five and ten (boys:  $p = 0.36$ ; OR = 1.55; 95% CI 0.60 to 3.98; girls:  $p = 0.14$ ; OR = 1.83; 95% CI 0.83 to 4.02) and boys over ten (boys:  $p = 0.97$ ; OR = 0.98; 95% CI 0.34 to 2.85), CT or US resulted in a non-significantly higher negative appendectomy rate. In girls over 10, CT or US resulted in a significantly higher negative appendectomy rate ( $p < 0.001$ ; OR = 1.97; 95% CI 1.42 to 2.74)<sup>90</sup>

## Score-Based Managements Versus Routine Management or Non-Score-Based Clinical Assessment

Four RCTs with a total of 657 participants compared the use of scores to routine management in the diagnosis of appendicitis and reported comparative effectiveness outcomes (Table 30).<sup>107-110</sup> One trial described both details of random sequence generation and an adequate

allocation concealment procedure,<sup>108</sup> and two trials described only details of random sequence generation.<sup>107,110</sup> The third did not describe randomization or allocation procedures.<sup>109</sup> No trial described blinding of outcome assessors and no trial described any loss to follow-up for any outcome.

Farahnak et al. (2007) randomized patients referred to the emergency service with an “impermanent” diagnosis of acute appendicitis to standard clinical management versus management according to the Alvarado score. They found significant differences in mean time to surgery and duration of hospitalization between patients randomized to either standard clinical management or management according to the Alvarado score. The mean time from randomization to surgery was statistically significantly less ( $p = 0.03$ ) in 10 patients in the Alvarado group ( $6.39 \pm 9.93$  hours; median 2.05, min 0.4, max 32.4, IQR 7.39) than in 10 patients in the standard care group ( $11.09 \pm 10.04$  hours; median 8.35, min 2.4, max 37.1, IQR 5.55). Mean length of stay was also shorter in the 21 patients in the Alvarado group ( $42.61 \pm 62.48$  hours; median 37 hours, min 0.3, max 290.5, IQR 58.4) than in the 21 patients in the standard care group ( $66.27 \pm 61.89$  hours; median 60.40, min 0.3, max 280.2, IQR 40.7) ( $p = 0.034$ ). The perforation rate was similar in the two groups (1 of 21, 4.8% in the Alvarado group; 0 of 21, 0% in the standard care group;  $p > 0.99$ ).<sup>107</sup>

In two separate trials, Lintula et al. evaluated the Lintula score in pediatric (2009) and adult (2010) populations. In the pediatric population, the negative appendectomy rate was lower in the Lintula score group (17%; 5 of 29) than in the standard clinical assessment group (29%; 11 of 38;  $p = 0.05$ ). Perforation rates were similar (21 of 66, 32% in the score group; 24 of 60, 40% in the standard clinical assessment group;  $p = 0.36$ ). The score group had a perforation rate of 88 percent (21 of 24) and an abscess rate of 8.3 percent (2 of 24), and the standard clinical assessment group had a perforation rate of 89 percent (24 of 27) and an abscess rate of 8.3 percent (2 of 27). Mean length of hospital stay was also reported as not significant. The mean length of stay in the score group was  $2.7 (\pm 1.8)$  days, and the mean length of stay in the standard clinical assessment group was  $2.9 (\pm 1.1)$  days. There were no deaths in either group, but one patient in each group had a post-surgical wound infection.<sup>108</sup> In adults, they also found non-significant differences between the groups in terms of negative appendectomy rate, number of perforations or abscesses, and length of stay. The negative appendectomy rate (8 of 60, 13% in the score group vs. 7 of 43, 16% in the standard assessment group;  $p = 0.78$ ), the perforation rate (3 of 60, 5% in the score group; 3 of 43, 7% in the standard assessment group;  $p = 0.69$ ), and the abscess rate (2 of 60, 3% in the score group; 0 of 43, 0% in the standard assessment group;  $p = 0.51$ ). The mean length of stay was  $2.2 (\pm 1.8)$  days in the score group as compared to  $2.3 (\pm 2.6)$  days in the standard clinical assessment group.<sup>109</sup>

Shah et al. (2008) randomized a group of 308 patients (both adults and children) who had a provisional diagnosis of appendicitis to an intervention group (Alvarado score and US based on the results of the score assessment) versus a control group of “clinical diagnosis”. In the intervention group patients with an Alvarado score of 3 or less did not undergo ultrasound, those with a score of 4 to 8 underwent US, and those with a score of 9 or 10 were deemed candidates for surgery and US was optional. Patients in the control group were not evaluated with the Alvarado score and did not undergo US. The authors found that average length of stay (61.3 hours in the intervention group and 62.5 hours in the control group), the rate of non-therapeutic operations (1.3% vs. 4.4%), the rate of delayed treatment and perforation (3.3% vs. 1.9%), and the rate of all adverse outcomes (delayed treatment in association with perforation and non-

therapeutic operations, 4.7% vs. 6.3%) were not statistically significantly different between groups.

One NRCS<sup>111</sup> with 1,484 participants reported comparative effectiveness outcomes. They reported that the negative appendectomy rate was higher in patients who had a diagnostic score as part of their workup (10.2%; 13 of 127) compared to those who did not (8.4%; 18 of 214), but the difference was not significant ( $p = 0.57$ ). The negative laparotomy rate was lower in patients who had a diagnostic score as part of their workup (3.4%; 8 of 233) compared to those who did not (3.9%; 14 of 358), but again the difference was not significant ( $p = 0.83$ ). There were fewer perforated appendixes in the scores group (14.9%; 17 of 114) than in the non-scores group (19.4%; 38 of 196) ( $p = 0.32$ ). The scores group had a significantly lower delayed appendectomy ( $\geq 2$  days) rate (1.8%; 2 of 114 vs. 7.7%; 15 of 196 in the non-scores group;  $p = 0.03$ ), as well as a significantly lower delayed discharge ( $\geq 10$  days) rate (11.4%; 13 of 114 vs. 21.6%; 43 of 199 in the non-scores group;  $p = 0.02$ ).<sup>111</sup>

**Table 30. Randomized comparisons of scores versus no scores with respect to clinical outcomes and resource utilization**

Comparison	Author, Year [PMID]	Outcome	Outcome Rate or Mean in Group 1	Outcome Rate or Mean in Group 2	Between-Group Difference*
Alvarado vs. standard practice	Farahnak, 2007 [17870498]	Duration of hospitalization	42.61 hours (62.48)	66.27 hours (61.89)	-23.66 hours (-61.27 to 13.95); p = 0.218
		Perforations	0/21 (0.0%)	1/21 (4.8%)	-0.05 (-0.17 to 0.07); p = 0.446
		Time to Surgery	6.39 hours (9.93)	11.09 hours (10.04)	-4.70 hours (-12.23 to 2.83); p = 0.221
Pediatric score vs. standard practice	Lintula, 2009 [18841382]	Deaths	0/66 (0.0%)	0/60 (0.0%)	0 (-0.03 to 0.03); p = 1.00
		Length of Stay	2.70 days (1.80)	2.90 days (1.10)	-0.20 days (-0.72 to 0.32); p = 0.447
		Negative appendectomy	5/66 (7.6%)	11/60 (18.3%)	-0.12 (-0.32 to 0.08); p = 0.249
		Perforations	21/66 (31.8%)	24/60 (40.0%)	-0.08 (-0.25 to 0.09); p = 0.338
Pediatric score vs. standard practice	Lintula, 2010 [20379739]	Negative appendectomy	8/96 (8.3%)	7/81 (8.6%)	-0.03 (-0.17 to 0.11); p = 0.680
		Perforations	3/96 (3.1%)	3/81 (3.7%)	-0.01 (-0.06 to 0.05); p = 0.833
Alvarado + US depending on the score value vs. standard practice	Shah, 2008 [not indexed]	Length of stay	61.3 hours (NR)	62.5 hours (NR)	0.9 hours (no additional information reported)
		Delayed treatment and perforation	5/150 (3.3%)	3/158 (1.9%; this percentage was reported as 11.91% in the paper but that number was inconsistent with the count of events provided in tables and in the text)	0.014 (-0.0 to 0.05); p = 0.432
		Non-therapeutic operations	2/150 (1.3%)	7/158 (4.4%)	-0.031 (-0.06 to 0.006); p=0.101
		Delayed treatment in association with perforation and non-therapeutic operations	7/150 (4.6%)	10/158 (6.3%)	-0.017 (-0.067 to 0.034); p=0.521

NR = not reported

\*Risk difference for binary outcomes; mean difference for continuous outcomes. Values in parentheses are 95% confidence intervals. For continuous outcomes, p-values are missing when studies did not report adequate data to calculate them.

## Diagnostic Laparoscopy Versus Open Diagnostic Exploration

Bruwer (2003) compared the use of diagnostic laparoscopy to open diagnostic exploration in a RCT of 34 premenopausal women (15 to 45 years old) in whom a decision to perform surgical exploration made.<sup>112</sup> The trial described random sequence generation procedures, but did not describe procedures for allocation concealment or blinding of outcome assessors. No participants were lost for any other outcomes. They found that there were fewer negative appendectomies in the diagnostic laparoscopy group (2 of 11) than in the open appendectomy group (7 of 16), but the difference was not statistically significant ( $p=0.23$ ). The difference in length of stay was reported not to be significant, though the laparoscopy group had a slightly shorter mean length of stay ( $3 \pm 1.6$  days) than the open group ( $3.7 \pm 1.1$  days).

One NRCS<sup>113</sup> of 1899 patients compared the diagnostic performance (see Key Question 1) and complications of laparoscopic (1043 patients) versus open (856) approaches for patients with presumed acute appendicitis. The authors found that the laparoscopic approach had a higher rate of intra-abdominal abscess formation (3.9% vs. 2.2%;  $p=0.055$ ) and lower rate of wound infection (1.5% vs. 7%;  $p<0.001$ ) compared to the open approach.

## Diagnostic Laparoscopy Versus No Laparoscopy

Three RCTs<sup>114-116</sup> with a total of 334 participants compared the use of diagnostic laparoscopy to routine management in the diagnosis of appendicitis and reported comparative effectiveness outcomes. Two of the trials did not describe random sequence generation procedures, procedures for allocation concealment, or blinding of outcome assessors.<sup>114,116</sup> The other described adequate random sequence and allocation concealment procedures, but did not describe blinding.<sup>115</sup> One study reported fewer than 90% of participants were followed for well-being outcomes, but no participants were described as lost for any other outcomes.<sup>114</sup> The others reported no participants lost for any outcomes extracted in this review.<sup>115 116</sup>

Decadt et al. reported that participants randomized to early laparoscopy had a median time to operation of 10 hours (min 2, max 39), while those randomized to active observation and noninvasive investigation had a median time to operation of 39 hours (min 15, max 119). Length of hospital stay was two days (min 1, max 13) in each group ( $p = 0.87$ ).<sup>114</sup> Gaitan et al. reported that the time to diagnosis was shorter in the group that had laparoscopy within 24 hours of admission ( $1.41 \pm 1.06$  days) than in the group that had clinical observation and conventional diagnosis ( $2.32 \pm 2.3$  days).<sup>115</sup> Morino et al. reported that the mean time to operation was 7.5 hours in the immediate laparoscopy group compared to 69.1 ( $\pm 50.9$  hours) the observation group, and the mean duration of hospital stay was shorter ( $3.7 \pm 0.8$  days) in the immediate laparoscopy group when compared to the observation group ( $4.7 \pm 2.4$  days).<sup>116</sup>

## Diagnostic Laparoscopy Versus Immediate Appendectomy

Six RCTs, all enrolling women of reproductive age, with a total of 461 participants compared the use of diagnostic laparoscopy to immediate appendectomy and reported comparative effectiveness outcomes.<sup>117-122</sup> No trial described random sequence generation procedures, procedures for allocation concealment, or blinding of outcome assessors. All outcomes were reported for greater than 90% of participants in each trial.

All five studies that reported negative appendectomy rates found them to be lower in the diagnostic laparoscopy group compared to the immediate appendectomy group. Jadallah et al. (1994) reported a rate of 13.3 percent (4 of 30) in the diagnostic laparoscopy group compared to

36 percent (18 of 50) in the immediate open appendectomy group.<sup>117</sup> Laine et al. (1997) reported a rate of 5.9 percent (1 of 17) in the diagnostic laparoscopy group compared to 44 percent (11 of 25) in the immediate open appendectomy group.<sup>118</sup> Larsson et al. (2001) reported a rate of 9 percent (4 of 44) in the diagnostic laparoscopy group compared to 34 percent (18 of 55) in the immediate open appendectomy group. They reported that the relative risk of removing a healthy appendix was 6.6 (95% CI 2 to 21) for open compared to laparoscopic group.<sup>119</sup> Olsen et al. (1993) reported a rate of 7 percent (2 of 30) in the diagnostic laparoscopy group compared to 37 percent (11 of 30) in the immediate appendectomy group.<sup>120</sup> van Dalen et al. (2003) reported a rate of 4 percent (1 of 25) in the diagnostic laparoscopy group compared to 26 percent (8 of 31) in the immediate appendectomy group.<sup>121</sup>

Five studies also reported on length of stay. Jadallah et al. reported a slightly shorter median length of stay (2 days, min <1, max 7) in the diagnostic laparoscopy group compared to the immediate open appendectomy group (3 days, min 1, max 18). Mean length of stay was 2.33 and 3.1 days, respectively. The p-value was <0.001 when comparing laparoscopy alone (no appendectomy) to appendectomy without laparoscopy.<sup>117</sup> Laine et al. reported a slightly longer length of stay for diagnostic laparoscopy ( $2.7 \pm 0.3$  days) compared to immediate open appendectomy ( $2.3 \pm 0.1$  days).<sup>118</sup> Olsen et al. also reported a slightly longer length of stay for diagnostic laparoscopy (3.8 days; min 1, max 8) compared to immediate appendectomy (3.2 days; min 1, max 7;  $p = 0.25$ ).<sup>120</sup> van Dalen et al. reported a statistically significantly shorter mean length of stay for diagnostic laparoscopy (4 days; min 1, max 9) than immediate appendectomy (4.9 days; min 2, max 11;  $p = 0.01$ ).<sup>121</sup> Tzovaras et al. reported that both groups had a mean length of stay of two days, but the range for diagnostic laparoscopy was one to nine days, while it was one to seven days for open appendectomy.<sup>122</sup>

Four NRCS<sup>89,123-125</sup> with 5497 participants reported comparative effectiveness outcomes for diagnostic laparoscopy versus open appendectomy. All four studies reported on negative appendectomy rates. Barrat et al. reported that the negative appendectomy rate was significantly lower for those who had laparoscopy (8.2%; 24 of 290) than those who had open appendectomy (25.4%; 236 of 930) ( $p = 0.015$ ).<sup>125</sup> Wagner et al. also reported that the negative appendectomy rate was lower for those who had laparoscopy (7.3%) than those who had open appendectomy (8.4%), but it was not significant ( $p = 0.53$ ).<sup>89</sup> Akbar et al. reported a higher negative appendectomy rate in diagnostic laparoscopy participants (24.5%; 63 of 256) than in those that had open appendectomy (13% 178 of 1357).<sup>123</sup> Ekeh et al. also reported a significantly higher negative appendectomy rate in laparoscopy patients (23.3%) than in those that had open appendectomy (14%) ( $p < 0.001$ ).<sup>124</sup> Only one study reported on time from ED to surgery, which was significantly longer for laparoscopy participants (mean  $10.8 \pm 9$  hours) than for open appendectomy patients ( $9.75 \pm 8.5$  hours;  $p = 0.0333$ ).<sup>124</sup>

## **Clinical Outcomes and Resource Utilization in Pregnant Women With Suspected Acute Appendicitis**

Eight studies<sup>126-132,133</sup> reported information on clinical outcomes and resource utilization for pregnant women. These studies were mostly small and only a few gave comparative results.

Three studies reported negative appendectomy rates for pregnant women. One reported a negative appendectomy rate with MRI of 8 of 27.<sup>130</sup> A second reported a negative appendectomy rate of 1 of 20 in patients who first had US then MRI.<sup>133</sup> The third reported negative appendectomy rates of 7 of 13 for clinical evaluation, 20 of 55 for US, 1 of 13 for US and CT,

and 3 of 5 for CT alone.<sup>126</sup> Only one study reported that repeat imaging was necessary; two MRI patients required repeat imaging to visualize contrast material in the cecum.<sup>131</sup>

Four studies reported information on delay in diagnosis. Two studies, one of MRI and the other of laboratory findings, reported that there were no delays caused by the diagnostic process or test findings.<sup>127,128</sup> A third study reported that operative delay due to diagnostic delay was significantly correlated with maternal morbidity.<sup>132</sup> and a fourth reported that there were three perforations due to diagnostic delay in a cohort of 36 patients.<sup>129</sup>

**Key Question 3: What are the harms of diagnostic tests per se, and what are the treatment-related harms of test-directed treatment for tests used to diagnose RLQ pain and suspected acute appendicitis?**

## **Included Studies With Information on Adverse Events**

Of 925 included studies, only 82 mentioned harms related to diagnostic tests: 17 RCTs<sup>76,78,82,83,91,93,94,97,110,112,114,116-118,120-122</sup>; 12 NRCS<sup>100,113,125,134-142</sup>; and 53 diagnostic cohort studies.<sup>129,132,143-193</sup> Eight (3 RCTs<sup>78,91,94</sup> and 5 diagnostic cohort studies<sup>159,162,165-167</sup>) reported an absence of adverse events for all tests except diagnostic laparoscopy (see Table 31). The fact that so few studies reported harms raises concerns about selective outcome reporting. The studies that mentioned at least one harm are included in Tables 32 to 35 and are discussed briefly below.

## **Contrast-Related Adverse Events**

Eight studies (3 RCTs<sup>76,83,97</sup> and 5 diagnostic cohort<sup>152,155,161,163,164</sup>) reported on adverse events related to contrast administration. Of these, three reported that the contrast was well tolerated.<sup>83,155,164</sup> Twelve studies of CT (of 247 included for Key Question 1), two of MRI (of 35), two of nuclear medicine (of 31), and one of US (of 301) reported data on contrast related harms. Full results by study are in Table 32.

Of the two RCTs that reported contrast-related harms, one reported five cases of vomiting after oral contrast in 152 patients, one in the group that got selective CT imaging (n=80) and four in the group that got CT imaging standard (n=72).<sup>76</sup> A second reported a mild skin rash after intravenous contrast administration that resolved spontaneously within 10 minutes in the CT group (n=317; n total = 600).<sup>97</sup>

In the diagnostic cohort studies, one reported that a single patient of 308 had Gastrografin-induced chemical pneumonitis; this patient required mechanical ventilation for three days and recovered completely.<sup>163</sup> Another reported that of 100 patients, there was leakage of colonic contrast material in 12 cases, nausea or vomiting three cases, and extravasation of intravenous contrast material one case.<sup>161</sup> A third reported that of 1561 patients given oral contrast before CT, 243 vomited at least once, 84 required nasogastric intubation, and the average wait time before CT scan was an hour longer (2 hours) than for those who did not have contrast.<sup>152</sup>

**Table 31. Studies that reported that no adverse events occurred**

Study Design	Study	Test	Contrast Route of Administration	N	Population	Summary
<b>RCT</b>	Mittal et al., 2004, 15136349 <sup>94</sup>	Standard vs. focused CT	IV, oral, rectal vs. rectal only	91	mixed	There were no complications as a result of the procedures in either group. No morbidities due to the CT scans were reported in either group.
	Lopez et al., 2007, 18186378 <sup>78</sup>	CT vs. clinical observation	oral, IV	95	women of childbearing age	No complications were associated with this radiologic protocol.
	Hersko et al., 2007, 17566826 <sup>91</sup>	Unenhanced vs. rectal contrast enhanced vs. IV and oral contrast enhanced CT	none used vs. rectal vs. IV and oral	232	adults	"CT-related complications, such as contrast material sensitivity reactions, aspiration, or renal failure, were not observed in any of the study groups." "All techniques were found to be safe and no CT-related complications were observed."
<b>Diagnostic cohort studies</b>	Brandt et al., 2003, 14509318 <sup>159</sup>	CT	oral, IV contrast	330	adults	There were no complications attributable to the CT scans obtained
	Johnson et al., 2012, 22623558 <sup>165</sup>	MRI	NR	42	children	All patients enrolled in the study were able to complete the examination.
	Leeuwenburgh et al., 2013, 23481162 <sup>162</sup>	CT and/or MRI	none used	230	adults	No adverse events occurred during imaging.
	Kipper et al., 2000, 10716317 <sup>166</sup>	Tc-99m	NR	49	mixed	No serious adverse events were attributable to LeuTech injection, and vital signs did not significantly change after injection. One patient with a history of asthma had a brief episode of shortness of breath 1 hour after injection that completely resolved without intervention. This occurrence was believed to be unrelated to the LeuTech injection because of timing and the manner in which it resolved.
	Wong et al., 1997, 9404876 <sup>167</sup>	Tc-99m	NR	51	mixed	No patients developed any side effects, adverse reactions, or complications.

CT = computed tomography; IV = intravenous; MRI = magnetic resonance imaging

Study Design	Study	Test	Contrast Route of Administration	N	Population	Summary
<b>RCT</b>	Lee et al., 2007, 17192450 <sup>76</sup>	CT	oral and IV	152	adults	Selective CT imaging: 1 case of recurrent vomiting secondary to oral contrast ingestion. Routine CT imaging 4 cases of recurrent vomiting secondary to oral contrast ingestion.
	Walker et al., 2000, 11182396 <sup>83</sup>	CT	rectal	65	adults	"Rectal contrast for the CT scan was well tolerated by the majority of patients. One patient refused more than 200 cc of rectal contrast and other received no contrast at all."
	Kaiser et al., 2002, 12034928 <sup>97</sup>	CT	IV	600	children	No severe adverse drug reactions. 1/600 = mild skin rash limited to the chest that resolved spontaneously within 10 minutes.
<b>Diagnostic cohort studies</b>	Hershko et al., 2002, 12455796 <sup>163</sup>	CT	oral and IV	308	adults	One case of Gastrografin-induced chemical pneumonitis. The patient required mechanical ventilation for three days and recovered completely.
	Kan et al., 2001, 11770917 <sup>164</sup>	CT or US, Hydrocolonic	rectal	31	adults	"All 31 patients were able to hold the rectally administered contrast material until completion of both hydrocolonic US and appendiceal CT."
	Laituri et al., 2011, 21470628 <sup>152</sup>	CT	oral	1561	children	Vomiting in 243, nasogastric intubation in 84, time to scan average 2 hours (estimated time to scan without contrast 1 hour).
	Rao et al., 1997, 8988203 <sup>155</sup>	CT	rectal	99	mixed	This bowel contrast medium regimen was well tolerated by our patients.
	Wise et al., 2001, 11264081 <sup>161</sup>	CT	oral, IV, rectal	100	adults	Leakage of rectal contrast in 12 cases, nausea or vomiting in 3 cases, extravasation of IV contrast material in 1 case

CT = computed tomography; IV = intravenous

## Exposure to Ionizing Radiation

No studies reported direct evidence on the effect of ionizing radiation on patient relevant outcomes.

Twelve studies (3 RCTs,<sup>82,93,116</sup> 4 NRCS,<sup>135,140-142</sup> and 5 cohort studies<sup>150,151,153,154,157</sup> reported radiation doses, and two of these<sup>154,157</sup> discussed strategies to reduce CT-related radiation exposure in a population (of a total of 247 CT studies included for Key Question 1). Reported mean CT radiation doses ranged from 7.2 to 15 mSv in adults;<sup>82,151,153,154</sup> in children, the mean reported dose was 4 mSv; and in a mixed-age population, the mean reported dose was 8 mSv.<sup>157</sup> Reported mean low-dose computed tomography (LDCT) radiation doses ranged from 1.2 to 4.2 mSv in adult and mixed populations.<sup>93,154,157</sup> Specific results for each study are in Table 33.

Both of the RCTs that reported evidence for this outcome in terms of CT compared standard CT radiation doses with radiation doses from another diagnostic modality. One RCT looked at the difference between low- and standard-dose CT in 891 participants and reported a median dose-length product for radiation from standard CT at 521 mGy x cm (IQR = 448-564); for LDCT, the median dose-length product for LDCT was about a quarter as much, at 116 mGy x cm (IQR = 94-124).<sup>93</sup> The second RCT compared current standard practice (plain radiography of the supine abdomen and erect chest, as well as CT if it was deemed necessary) with an early CT protocol that used abdominopelvic scans on a 16 detector scanner with intravenous contrast. The authors reported that the CT protocol had a mean radiation dose of 9 mSv, while the dose for the plain radiography was only 0.82 mSv.<sup>82</sup> The third RCT reported mean radiation dose for patients who either received immediate laparoscopy ( $1.1 \pm 1$  mSv) or underwent observation before laparoscopy ( $2.2 \pm 5.1$  mSv).<sup>116</sup>

Three retrospective NRCS and one prospective NRCS reported radiation doses between different arms of CT in mixed and pediatric populations. In 2011, Kim et al. reported the same radiation doses for CT and LDCT as in their 2012 RCT (standard CT: median dose-length product = 544 mGy x cm; LDCT: median dose-length product = 122 mGy x cm).<sup>135</sup> In a prospective NRCS, Karabulut et al. compared low-dose dual slice CT versus multidetector row CT in a mixed population. They found similar calculated mean effective radiation doses between low-dose CT (1.2 and 2.2 mSv for male and female patients, respectively) and multidetector CT (1.5 and 2.0 mSv for male and female patients, respectively).<sup>142</sup>

In 2014, Didier et al. reported lower radiation doses in a pediatric population with a change in CT protocol in 2010. The mean size-specific dose estimate and volume CT dose index with the standard protocol between 2008 and October 18, 2010 were 12.6 mGy (SD 2.5 mGy) and 7.3 mGy (SD 2.3 mGy), respectively. Between October 19, 2010 and 2012, the scans were performed using iterative reconstruction technique software, and the mean size-specific dose estimate and volume CT dose indexes dropped to 6.8 mGy (SD 2.6 mGy) and 4 mGy (SD 2 mGy), respectively ( $p < 0.0001$ ).<sup>140</sup> Sharp et al. reported lower CT radiation doses in children in children's versus outside hospitals. The mean dose length product was 143.54 mGycm (SD 41.19 mGycm) in the children's hospital as compared to 586.25 mGycm (SD 521.59 mGycm) in the outside hospital ( $p < 0.001$ ); the mean volume computed tomography dose length index was 4.89 mGy (SD 2.64 mGy) in the children's hospital and 16.98 mGy (SD 15.58 mGy) in the outside hospital ( $p < 0.001$ ); and the mean size-specific dose estimate was 3.81 mGy (SD 2.02 mGy), in the children's hospital and 26.71 mGy (SD 23.1 mGy) in the outside hospital ( $p < 0.001$ ).<sup>141</sup>

There were five diagnostic cohort studies reporting on this outcome. One study in which everyone first had a LDCT then a standard CT reported a total radiation dose of 12.2 mSv (8

mSv from the standard CT plus 4.2 mSv from the low-dose CT).<sup>157</sup> A second study reported on the evaluation of an algorithm, in which patients were first evaluated by US then, in the case of indeterminate US findings or negative US findings with high clinical suspicion of appendicitis, the patient received a low-dose CT exam. If the low-dose CT exam was indeterminate, the patient had a standard CT. The authors of this study reported an actual mean dose with the algorithm of 3.23 mSv, which was significantly lower ( $p < 0.0001$ ) than the hypothetical mean dose if a standard CT had been systematically performed at admission (9.02 mSv).<sup>154</sup> One study of pregnant women reported a mean radiation dose of 16 mGy (range 4 to 45 mGy) for CT.<sup>191</sup>

**Table 33. Reported radiation dose**

Study Design	Study	Test	Contrast Route of Administration	N	Population	Radiation Dose (Mean)
<b>RCT</b>	Kim et al., 2012, 22533576 <sup>93</sup>	CT vs. LDCT	IV	891	mixed	Standard CT: median dose-length product = 521 mGy x cm (IQR = 448-564); low-dose CT: median dose-length product = 116 mGy x cm (IQR = 94-124)
	Sala et al. <sup>82</sup>	CT vs. XRAY	IV	99	adults	CT = 9 mSv; XRAY = 0.82 mSv

## Maternal/Fetal Adverse Events

Six studies (3 studies of US, of 301 included for Key Question 1); 3 of MRI (of 35); and 2 of multiple clinical and lab tests (of 217); some studies evaluated more than one test) reported information on maternal outcomes. One study of MRI reported that 17 patients without appendicitis progressed to uneventful labor and delivery.<sup>188</sup> A second study of MRI reported that not using oral contrast sped up the imaging process.<sup>189</sup> Four reported that there was no maternal mortality.<sup>129,185-187</sup>

Seven studies (5 studies of US (of 301); 2 of MRI (of 35); 1 of CT (of 247); and 1 of clinical symptoms and signs (of 137); some studies evaluated more than one test) reported information on fetal outcomes. Barloon et al. in a study of US reported that 18 of 22 patients had a normal term delivery; there were two spontaneous abortions (in patients with no clinical or sonographic evidence of acute appendicitis) and two elective abortions.<sup>185</sup> Kapan et al. in a study of US and several clinical and laboratory tests reported that all 20 women delivered healthy infants.<sup>186</sup> Lim et al. in a study of US only reported fetal outcomes for two of the 45 participants. One was a spontaneous abortion in a case of surgically confirmed acute appendicitis without perforation, and the other was a premature delivery in a patient with no evidence of appendicitis at followup through delivery.<sup>187</sup> Fonseca et al. reported on a clinical/US pathway versus MRI in 75 patients. They reported a total of nine adverse fetal outcomes (5/31 who had MRI and 4/44 in the US or clinical group), none were in the perioperative period (OR 1.09, 95% CI 0.90-1.31;  $p = 0.47$ ).<sup>194</sup>

Freeland et al. reported outcomes for US, MRI, and CT. In the US group, one patient, who had an open appendectomy in the first trimester, developed severe preeclampsia and had a premature delivery at 33 weeks (this patient also had a diagnostic CT), there was one fetal demise after a negative open appendectomy, but neither the fetal demise nor the early delivery was related directly to the appendectomy, and one patient with perforated appendicitis had abruptio-placentae and vaginal hemorrhage. Only one patient had MRI, and she delivered a healthy baby at term. Among thirteen patients who had a diagnostic CT, nine delivered healthy infants, one who had an open appendectomy in the first trimester developed severe preeclampsia and had a premature delivery at 33 weeks (see above), and three were lost to followup.<sup>190</sup> Lazarus et al. reported fetal outcomes for 55 of 80 patients who had CT. Fifty-one had a live infant at or near term, one had a premature delivery of a live 30-week infant three days after CT-diagnosed gastric cancer, two had spontaneous vaginal delivery of a nonviable fetus (one at 18 weeks with sepsis after normal CT and normal laparotomy, and one at 22 weeks with chorioamnionitis, 5 days after normal CT). There was one fetal demise at 26 weeks (four weeks after a CT examination with normal findings).<sup>191</sup> Tamir et al. reported that on a group evaluated on symptoms and signs, there were seven therapeutic abortions, two perioperative spontaneous abortions (first trimester), and four without appendicitis had severe perinatal morbidity or mortality.<sup>132</sup> Two studies of MRI reported on other harms in pregnant women. One reported that “all 12 patients and fetuses were exposed to unknown bioeffects of MRI.”<sup>127</sup> The other reported that patient tolerance of the MRI environment represents an additional concern in terms of successful implementation, but noted that only one patient refused to complete the MRI protocol.<sup>130</sup>

## Other Adverse Events of Imaging Tests

One RCT<sup>110</sup> and six diagnostic cohort studies<sup>156,158,160-162,193</sup> reported on a variety of other adverse events. For details by study, see Table 34.

In an RCT of standard clinical management versus an Alvarado/US pathway, Shah et al. found that a delay of over 10 hours from randomization to operation was associated with perforation in 5 of 100 patients in the US/Alvarado group and 3 of 110 patients in the clinical management group. They also noted two complications: a subcutaneous abscess in the scar in the intervention group and a subacute intestinal obstruction in the control group.

One reported that one child in a sample of 94 was unable to tolerate the CT procedure;<sup>158</sup> they did not give any further details. A second study measured discomfort in 100 patients who underwent US and CT on a scale of 0-10, where 10 was the most discomfort. The imaging pathway for half of the patients was oral contrast administration, then US, then unenhanced CT, then CT with intravenous contrast, then CT with colonic contrast material, then US; in the other half of patients, this order was reversed. They found that in general US produced more discomfort (average scores of 6.1 with oral contrast and 6.7 with oral, intravenous, and rectal contrast) than CT (average score 4.2 in focused scans with oral contrast, 6.7 in focused scans with oral, IV, and rectal contrast, and 5.3 in abdominopelvic scans with oral and intravenous contrast).<sup>161</sup> A study of Tc-99m labeled white blood cells reported that “of the 203 patients injected with LeuTech, 17 (8%) reported 20 mild and 4 moderate adverse events. None of these events were reported as definitely drug related. The most commonly reported adverse events were vasodilation (n=8), dyspnea (n=3), syncope (n=2), headache (n=2), and dizziness (n=2). Nine (4.4%) patients experienced significant changes in vital signs; however, none was assessed as drug related.”<sup>156</sup> In a study of rectal examinations, a rectal examination proved impossible on five of 328 occasions. Eighty children experienced severe and 121 minor discomfort during rectal examination at the time of hospital admission; at the examination before hospital discharge, severe discomfort was found in 34 and minor discomfort in 88 children.”<sup>160</sup> Leeuwenburgh et al. reported that seven patients could not complete the MRI procedure because of claustrophobia or unexpected technical failure;<sup>162</sup> they did not report how many of them had a claustrophobic reaction or give any further details. A final study reported on the results of a survey sent to 104 children after US and MRI. Of the total 52 that responded, 52 percent reported that MRI had a long duration, 10 percent found it painful, 53 percent reported tolerance, 32.7 percent found lying on the MRI gantry as burdensome, and 55.8 percent reported a preference for MRI over US immediately following the procedure; that number dropped to 51.8 percent after 3 months.<sup>193</sup>

**Table 34. Other adverse events**

Study Design	Study	Test	Contrast Route of Administration	N	Population	Summary
RCT	Shah et al., 2008 [not indexed in PubMed] <sup>110</sup>	US/Alvarado vs. clinical	N/A	308	mixed	Delayed treatment (operated after 10 hours from randomization) in association with perforation: 5 perforations in Alvarado/US vs, 3 in clinical group. Intervention group: 1 subcutaneous abscess; clinical group: 1 intestinal obstruction.
Diagnostic cohort studies	Acosta et al., 2005, 15633057 <sup>158</sup>	CT	rectal	94	children	One child was unable to tolerate the procedure.
	Dickson et al., 1985, 4026364 <sup>160</sup>	rectal exam	NR	201	children	A rectal examination was impossible in 5/328 exams. Admission examination: severe discomfort in 80, minor discomfort in 121. Discharge examination: severe discomfort in 34, minor discomfort in 88.
	Rypins et al., 2002, 11807363 <sup>156</sup>	Tc-99m	NR	248	mixed	No serious or severe adverse events were reported. 17/203 reported 20 mild and 4 moderate adverse events (none definitely drug related). The most commonly reported adverse events were vasodilation (8), dyspnea (3), syncope (2), headache (2), and dizziness (2). Nine patients experienced significant changes in vital signs (none drug related).
	Leeuwenburgh et al., 2013, 23481162 <sup>162</sup>	MRI	none used	223	adults	"In seven patients, an MR examination could not be performed because of claustrophobia or unexpected technical failure."
	Wise et al., 2001, 11264081 <sup>161</sup>	oral contrast administration, then US, then unenhanced CT, then CT with IV contrast, then CT with colonic contrast material, then US – in the other half of patients, this order was reversed	oral, IV, rectal	100	adults	Average discomfort score: CT: 4.2 in focused scans with oral contrast, 6.7 in focused scans with oral, IV, and rectal contrast, and 5.3 in abdominopelvic scans with oral and IV contrast. US: 6.1 with oral contrast and 6.7 with oral, IV, and rectal contrast.
	Cobben, 2004, 15333354 <sup>127</sup>	MRI	no contrast	12	pregnant women	All 12 patients and fetuses were exposed to unknown bioeffects of MRI.
	Pedrosa, 2009, 19244044 <sup>130</sup>	MRI	oral	148	pregnant women	One patient refused to complete the MRI protocol
	Thieme, 2014, 24135892 <sup>193</sup>	MRI	none used	104	children	Patients returning the survey reported on the following parameters: long duration = 58% (30/52), painful = 10% (5/52), tolerance = 53% (28/52), lying on the MRI gantry as burdensome = 32.7% (17/52), preference for MRI over US = 55.8% (29/52) immediate and 51.8% (27/52) after 3 months

CT = computed tomography; IV = intravenous; MRI = magnetic resonance imaging; RCT = randomized controlled trial

## Surgical Complications Related to Diagnostic Laparoscopy

Thirty-four studies of diagnostic laparoscopy (of 55 included for Key Question 1) mentioned surgery related harms. Eight RCTs (469 patients) and eight NRCSs (4084 patients) described complications related to laparoscopy as compared to open appendectomy; twenty-five diagnostic cohort studies (5553 patients) reported on complications of diagnostic laparoscopy. In general the rates of specific complications were low (generally less than 10% and in most cases less than 2%); however, few studies attributed specific adverse events to diagnostic laparoscopy (as opposed to additional surgical intervention). Nine studies, including five RCTs, reported that there were no complications related to the diagnostic laparoscopic procedure.

Four RCTs reported no complications or adverse events in the study group that had diagnostic laparoscopy.<sup>117,118,120,121</sup> Two of these studies reported harms that were not caused by the laparoscopic part of the operation: one postoperative ileus and two wound infections.<sup>117,118</sup> One RCT compared immediate laparoscopy with observation. Morino et al. reported that in the immediate laparoscopy group there was no mortality, one urinary tract infection, and one trocar site infection. In the observation group, there was also no mortality, and adverse events were limited to a single case of severe anemia.<sup>116</sup> Three RCTs compared laparoscopic versus open surgery. One RCT reported that in the laparoscopy group, one patient of 18 had spillage of purulent matter into the lower abdomen; in the open appendectomy group there were two wound infections and one adhesive small bowel obstruction in 16 patients.<sup>112</sup> Another RCT reported laparoscopy complications in 14 of 59 patients, including abdominal pain that persisted for at least one month after discharge (n=7), wound infection (n=5), wound dehiscence after laparotomy (n=1), readmission with respiratory symptoms and shoulder tip pain (n=1), and death from a massive pulmonary embolus 5 days after laparotomy despite full thromboprophylaxis. In the open group, 19 of 61 patients had complications, including abdominal pain persisting for at least 1 month (n=15), wound infection (n=4), and one death seven days after discharge from a presumed pulmonary embolism.<sup>114</sup> The third RCT reported more harms with laparoscopic surgery than open, including wound infections (4 of 59 in the early laparoscopic group and 3 of 61 in the open group), one trocar site hematoma, three pelvic collections, and one case of DVT in the laparoscopic group and 1 urinary retention in the open group.<sup>122</sup>

Eight NRCS described complications related to laparoscopy as compared to open appendectomy. One reported only that there was no mortality in either group.<sup>125</sup> The second reported that there were no intraoperative complications in either group, but that in the diagnostic laparoscopy group the complication rate was 6.6 percent (n=376). In the group that got an operation immediately, the complication rate was higher, 12.3 (n=124) percent. Specifically, the superficial wound infection rate was significantly lower in the diagnostic laparoscopy group than in the primary open surgery group ( $p = 0.020$ ), while the intra-abdominal infection rate did not differ between the groups ( $t9 = 0.15$ ). One patient in the laparoscopic appendectomy group required reoperation for mesoappendix bleeding, three were readmitted within 30 days after surgery because of intra-abdominal infection and three were converted to open appendectomy group because of subileus (no operation needed), prolonged pyrexia, or intestinal fistula. One patient in the laparoscopy group died, a 93-year-old woman who was discharged in good condition 6 days after a laparoscopic appendectomy but died in her home 12 days after surgery for unknown reasons.<sup>139</sup> A third study reported no complications of any type in the six patients who had diagnostic laparoscopy alone. In the 54 patients who had open appendectomy, there were five wound complications and one death. In the 47 patients who had diagnostic laparoscopy followed by laparoscopic appendectomy there were two wound complications. In the 15 patients

who had laparoscopy and open appendectomy there were two wound complications.<sup>183</sup> A recent comparative study of 1043 patients reported that the laparoscopic approach had a higher rate of intra-abdominal abscess (3.9% compared with 2.2% in the open group;  $p=0.055$ ), but a lower rate of wound infections (1.5% versus 7% for the open group;  $p<0.0001$ ).<sup>113</sup> Another NRCS comparing diagnostic laparoscopy and open appendectomy reported that among the 93 diagnostic laparoscopy patients, there were three wound infections, one ileus, one hemolytic anemia, one case of aspiration pneumonia, and one infected hydrocele. In the open appendectomy group ( $n=74$ ), there were four wound infections, two ileus, and one UTI.<sup>136</sup> Two other NRCS reported perforations, one of the small bowel,<sup>138</sup> and one of the transverse colon with the pneumoneedle.<sup>137</sup>

Twenty-five diagnostic cohort studies<sup>143-149,168-184,192</sup> reported on complications of diagnostic laparoscopy in 5469 patients. Five studies reported that there were no complications.<sup>143,146,173,175,184</sup> Two studies reported a total four deaths<sup>145,147</sup>. Others reported 37 wound infections,<sup>145,147-149,170-172,176-179,182</sup> 27 cases of ileus,<sup>145,171,172,177,182</sup> 23 deep venous thromboses,<sup>145</sup> 22 cases of fever (one with acute abdominal pain),<sup>145,147,172</sup> 18 intrabdominal infections,<sup>145</sup> 17 hematomas (4 wound, 2 intraabdominal, 2 abdominal wall, 1 parietal, and 8 unspecified),<sup>145,147,179,181</sup> 14 abscess,<sup>144,147,148,171,177,182</sup> 13 chest or respiratory infections,<sup>145,147,168,176,177,182</sup> six perforations (3 bowel and 3 bladder),<sup>170,171,177,180</sup> six fluid collection,<sup>174,176,178</sup> six bleeding or hemorrhage,<sup>145,168,177,181</sup> six intestinal obstructions,<sup>147,177</sup> five coronary related complications,<sup>145</sup> three inferior epigastric artery injury,<sup>172,180</sup> three appendix ruptured on removal,<sup>172</sup> two intestinal lesions,<sup>145</sup> two cases of cecal leakage,<sup>177</sup> one cecal dehiscence,<sup>177</sup> one insufflation in cecal wall,<sup>181</sup> one cecal phlegmon,<sup>147</sup> one appendiceal artery hemorrhage,<sup>147</sup> a perioperative arrhythmia and a pneumothorax,<sup>176</sup> one case of pancreatitis,<sup>147</sup> one case of intraabdominal sepsis,<sup>147</sup> a laryngeal spasm post-intubation,<sup>182</sup> a reaction to the abdominal sutures,<sup>174</sup> one tertiary peritonitis and enterocutaneous fistula,<sup>148</sup> a minor abdominal wall cellulitis,<sup>144</sup> one case of mesoappendiceal bleeding,<sup>145</sup> one pseudomembranous enterocolitis,<sup>145</sup> one pulmonary embolism,<sup>145</sup> one ruptured aortic aneurysm,<sup>145</sup>, and one reoperation to repair the appendix stump.<sup>192</sup> Further details are presented in Table 35.

**Table 35. Reported surgical complications of diagnostic laparoscopy**

Study Design	Study	N	Population	Summary of Surgical Complications
<b>RCTs</b>	Laine et al., 1997, 9069134 <sup>118</sup>	25	women of childbearing age	No complications related to laparoscopy. 1 postoperative ileus (not caused by the laparoscopic part of the operation).
	Olsen et al., 1992, 8369940 <sup>120</sup>	30	women of childbearing age	No complications related to laparoscopy.
	Jadallah et al., 1994, 8186313 <sup>117</sup>	100	women of childbearing age	No complications related to laparoscopy; 2 wound infections in laparoscopic appendectomy group.
	Van Dalen et al., 2003, 12739123 <sup>121</sup>	63	women of childbearing age	No complications related to laparoscopy.
	Bruwer et al., 2003, 14768141 <sup>112</sup>	34	women of childbearing age	Laparoscopy: 1 spillage of purulent matter into the lower abdomen. Open appendectomy: 2 wound infections, 1 adhesive small bowel obstruction.
	Decadt et al., 1999, 10583282 <sup>114</sup>	59	adults	Laparoscopy: 7 abdominal pain that persisted for at least 1 month after discharge, 5 wound infections, 1 wound dehiscence after laparotomy, 1 readmission with respiratory symptoms and shoulder tip pain, and 1 death from a massive pulmonary embolus 5 days after laparotomy. Open appendectomy: 15 abdominal pain persisting for at least 1 month, 4 wound infections, and 1 death 7 days after discharge from a presumed pulmonary embolism.
	Tzovaras et al., 2007, 17219281 <sup>122</sup>	54	mixed	Laparoscopy: 4 wound infections, 1 trocar site hematoma, 3 pelvic collections, 1 DVT. Open: 3 wound infections, 1 urinary retention
	Morino et al., 2006, 17122613 <sup>116</sup>	104	adults	Immediate laparoscopy: 1 urinary tract infection, 1 trocar site infection; observation 1 severe anemia.
<b>NRCSSs</b>	Ragland et al., 1988, 2792080 <sup>137</sup>	21	women of childbearing age	1 perforation of the transverse colon with the pneumoneedle
	Tronin et al., 1996, 9050636 <sup>138</sup>	1000	mixed	1 perforation of the small bowel
	Moberg et al., 2000, 1180408 <sup>139</sup>	500	adults	No intraoperative complications were seen in either group. Laparoscopy: complication rate = 6.6%, 1 reoperation for mesoappendix bleeding, 3 readmitted within 30 days because of intra-abdominal infection, 3 converted to open appendectomy, 1 death. Primary open appendectomy: complication rate = 12.3%.
	Schirmer et al., 1992, 8506965 <sup>139</sup>	68	mixed	No complications of any type with diagnostic laparoscopy alone (n=6); open appendectomy (n=54): 1 death, 5 wound complications, 18.9% complication rate; diagnostic laparoscopy + laparoscopic appendectomy (n=47): 2 wound complications, 10.6% complication rate; laparoscopy + open appendectomy (n=15): 2 wound complications, 46.7% complication rate.
	Barrat et al., 1999, 9950123 <sup>125</sup>	1285	adults	No mortality in either group.
	Kollias et al., 1994, 7980256 <sup>136</sup>	167	mixed	Laparoscopy (n=93): 3 wound infections, 1 ileus, 1 hemolytic anemia, 1 aspiration pneumonia, 1 infected hydrocele. Open (n=74) 4 wound infections, 2 ileus, 1 UTI.
	Sadot et al., 2013, 24016703 <sup>113</sup>	1899	mixed	Laparoscopy (n=1043): 41 intra-abdominal abscess, 16 wound infections; Open and laparoscopy (n=1899) 9 small bowel obstructions, 1 inadvertent enterotomy, 1 required reoperation for leakage from the cecum resection line, 1 small bowel obstruction, 1 intractable abdominal pain

**Table 35. Reported surgical complications of diagnostic laparoscopy (continued)**

Study Design	Study	N	Population	Summary of Surgical Complications
Diagnostic cohort studies	Ng et al., 2008, 18259838 <sup>182</sup>	787	mixed	1 wound infection, 1 intra-abdominal abscess, 1 ileus, 1 respiratory tract infection, 1 laryngeal spasm post-intubation
	Clarke et al., 1986, 2937361 <sup>170</sup>	46	adults	1 wound infection and 1 minor tear of the small bowel
	Cristalli et al., 1991, 1839575 <sup>173</sup>	31	mixed	No post-operative complications
	Spirtos et al., 1987, 2948388 <sup>184</sup>	86	women of childbearing age	No complications from laparoscopy; laparotomy: 4 wound infections, 2 pelvic abscess, 1 pulmonary embolism, 1 ileus
	Diehl et al., 1981, 6457704 <sup>175</sup>	25	mixed	no complications resulted directly from the procedure
	Cox et al., 1993, 8216060 <sup>172</sup>	81	mixed	5 operative complications: 3 appendix ruptured during manipulation, 1 left inferior epigastric artery was ruptured by the 5 mm LIF port, 1 extra peritoneal insufflation; 5 post-operative complications: 3 prolonged ileus, 1 fever, 1 wound infection
	Graham et al., 1999, 10615200 <sup>176</sup>	85	mixed	2 small intraperitoneal collections, 1 umbilical wound infection, 1 perioperative arrhythmia, 1 pneumothorax secondary to a patent pleuroperitoneal canal, 1 chest infection
	Borgstein et al., 1997, 9294274 <sup>169</sup>	161	women of childbearing age	1 bleeding from the trocar site, which required abdominal wall exploration
	Mutter et al., 1998, 9817258 <sup>181</sup>	36	mixed	No major complications. Minor complications: 1 insufflation in cecal wall, 1 preoperative hemorrhage on 2mm port site, 1 postoperative parietal hematoma required reoperation for removal
	in't Hof et al., 2004, 15386320 <sup>148</sup>	103	adults	3 wound infections, 2 intra-abdominal abscesses, 1 tertiary peritonitis and enterocutaneous fistula
	Lee et al., 2001, 11343547 <sup>149</sup>	76	mixed	1 wound infection
	DeCou et al., 2004, 14745576 <sup>174</sup>	30	children	1 suture reaction at the umbilical incision, 1 pelvic fluid collection
	Konstantinidis et al., 2008, 18373452 <sup>179</sup>	1024	mixed	Complication rate was 5.7% (52 patients), consisting mostly of minor complications. There were no major intraoperative complications. There were no intra-abdominal abscesses postoperatively. Wound-infection rate was 1.1%. We had 3 patients with an abdominal-wall hematoma at the trocar sites. Two of them were managed intraoperatively. The 3rd patient was treated conservatively after surgery. There was no mortality.
	Jones et al., 2011, 21688285 <sup>178</sup>	146	mixed	1 wound infection, 3 intra-abdominal collection
	Gurrado et al., 2009, 20334502 <sup>177</sup>	1024	Mixed	Minor: 1 wound infection, 1 pneumonia, 1 ilium. Major: 4 intraabdominal abscesses, 5 intestinal obstructions, 1 hemorrhage, 2 bowel perforation, 1 bladder perforation, 1 cecal dehiscence, 2 cecal leakage
	Linos et al., 1999, 10194691 <sup>180</sup>	121	women of childbearing age	2 injury to inferior epigastric artery, 1 bladder injury caused by suprapubic trocar

Study Design	Study	N	Population	Summary of Surgical Complications
<b>Diagnostic cohort studies (continued)</b>	Ates et al., 2008, 18373441 <sup>168</sup>	74	mixed	Other than a chest infection observed in 1 patient, there was no operative complication; no death and, postoperatively, none of our patients had a leak or residual intra-abdominal abscess in this study.
	Moberg, 1998, 9845129 <sup>145</sup>	1043	mixed	Perioperative complications: 2 intestinal lesions, 1 mesoappendiceal bleeding. Postoperative complications: 12 wound infections, 20 prolonged fever, 8 hematoma, 21 ileus, 23 DVT, 5 lung complications, 1 pseudomembranous enterocolitis, 18 intrabdominal infections, 3 bleeding, 1 pulmonary embolism, 5 coronary related complications, 3 deaths, 1 ruptured aortic aneurism
	Thorell, 1999, 10494640 <sup>143</sup>	77	women of childbearing age	No complications developed during the hospital stay
	Wagner, 1996, 8703146 <sup>147</sup>	267	mixed	4 wound infections, 4 wound hematoma, 4 pneumonia, 1 early obstruction, 1 pancreatitis, 1 intraabdominal hematoma, 5 abscess, 1 bleeding from appendiceal artery, 1 acute abdominal pain and fever, 1 cecal phlegmon, 1 intraabdominal sepsis, 1, death
	Bagnato et al., 1992, 1387169 <sup>144</sup>	23	mixed	1 postoperative pelvic abscess, 1 minor abdominal wall cellulitis
	Kuster, 1992, 1416436 <sup>146</sup>	38	adults	No morbidity or mortality
	Connor et al., 1994, 7856985 <sup>171</sup>	85	mixed	1 bladder perforation, 1 postoperative abscess, 1 prolonged ileus, 1 wound infection
	Ilce et al., 2013, 24353684 <sup>192</sup>	84	children	1 appendix stump was opened postoperatively and repaired by laparotomy 3 days after the first operation. No postoperative mortalities.

NRCS = nonrandomized comparative study; RCT = randomized controlled trial

# Discussion

## Key Findings and Strength of Evidence Assessment

This Comparative Effectiveness Review synthesizes evidence from more than 900 studies on the diagnosis of RLQ pain and suspected acute appendicitis to answer Key Questions related to test performance, patient-relevant outcomes, and test-related harms. The literature on the test performance of various clinical symptoms and signs, laboratory and imaging tests, and multivariable diagnostic scores is vast, but consists almost exclusively of studies assessing the test performance of individual index tests. Information on test performance of multiple tests applied jointly and conditional test performance (i.e., test performance among patients already examined with other tests) was very limited. The few studies that provided information on more than one index tests were typically not designed with the goal of providing comparative information and cross-study comparisons cannot provide reliable evidence on relative performance. We found very limited information on the test performance or comparative effectiveness of diagnostic pathways (i.e., well-defined sequences of diagnostic and treatment steps). Comparisons of the test performance of alternative test strategies had to rely on indirect (cross-study) evidence. We believe that the available evidence can support fairly strong conclusions about the test performance of individual tests, but is often insufficient to support conclusions about their comparative effectiveness. In this section we briefly summarize our assessment of the strength of evidence for key outcomes (Table 36). Of note, strength of evidence grades reflect our confidence in the evidence underlying the report's conclusions and should not be interpreted as clinical recommendations. For example, "insufficient" strength of evidence for a comparison between two tests means that the available evidence does not allow us to confidently estimate the difference in test performance between the two tests; it does not mean that we believe the tests to have (or not have) similar performance.

## Test Performance

Clinical symptoms and signs, including classical signs of peritoneal irritation, fever, and various assessments of abdominal pain, appeared to have limited test performance when used in isolation (positive likelihood ratios smaller than 5; negative likelihood ratios larger than 0.2) in all the populations of interest to this report. Among laboratory tests WBC, CRP, and tests derived from combinations of measurements on the complete blood count and differential had test performance that was generally higher compared to that of clinical symptoms and signs (especially with respect to sensitivity using a low risk threshold) but still rather limited (e.g., in terms of summary LR<sub>s</sub>). Because studies did not allow an examination of the performance of multiple tests applied jointly, and because conditional test performance was not reported uniformly across studies, the clinical implications of the relatively limited test performance of many non-imaging tests are not clear. Furthermore, signs and symptoms are variable within patient (over the course of disease) and among patients, and it is hard to assess their performance based on test performance. Importantly, the clinical examination forms the basis of the investigation of acute abdominal pain and suspected acute appendicitis and – even if poorly reported – all studies of imaging tests use some form of clinical examination for patient selection.

Multivariable diagnostic scores appeared to have test performance that was superior to the individual clinical signs, symptoms, or laboratory tests they included, but still rather limited

(e.g., in terms of summary likelihood ratios). Of note, the majority of studies assessed scores that had been developed before the widespread availability of CT and US imaging, suggesting that their results may be less applicable to current clinical practice.

Among imaging tests, CT and MRI had high sensitivity and specificity, resulting in clinically relevant summary likelihood ratios. CT had been investigated by a large number of diagnostic cohort studies, leading to precise estimates of test performance in all populations of interest to this report. Although there were no reported short-term harms from ionizing radiation, it does present a long-term risk, particularly in children and pregnant women. In contrast, MRI had been investigated in a relatively small number of studies mainly focused on pregnant women. US had lower test performance and resulted in substantially greater proportion of non-diagnostic examinations, compared to both CT and MRI, across populations of interest. US was investigated by a large number of studies and results were somewhat heterogeneous, suggesting that the average estimate of test performance may not apply to all populations for which US is considered. A possible explanation for this heterogeneity is the operator dependence of the test performance of US and the fact that studies had been conducted in different settings.

Diagnostic laparoscopy appeared to have good test performance; however, studies were poorly reported and differed in their policies regarding removal of the appendix when no pathology was macroscopically visible, which may bias test performance results. Furthermore, patients included in studies of diagnostic laparoscopy are different from patients included in studies of non-invasive tests. Therefore, our results for the test performance of laparoscopy should not be compared with the other diagnostic tests reviewed in this report.

For all diagnostic tests, we emphasize that test performance is not directly related to clinical outcomes, and high sensitivity and specificity do not necessarily imply improvements in outcomes, such as perforations, abscesses, or other infectious complications.

## **Comparative Test Performance**

Comparisons among tests with respect to test performance relied on a small number of RCTs of moderate risk of bias, a relatively small number of direct comparisons among index tests in diagnostic cohort studies that were not designed to obtain comparative information, and indirect comparisons across single index test studies enrolling diverse populations in heterogeneous clinical settings. There was evidence of moderate strength that CT has superior overall test performance compared to US and produces fewer non-diagnostic results. Similarly, MRI appeared to have better test performance than US, but the strength of evidence was deemed low. The strength of the evidence on comparisons among other imaging tests and among multivariable diagnostic scores was deemed insufficient.

## **Patient-Relevant Outcomes**

The evidence is insufficient for patient relevant outcomes. We based our assessment of the comparative effectiveness of alternative tests primarily on RCTs because indirect (across studies) comparisons of outcomes other than test performance are susceptible to bias due to differences among the populations included. We found only a few RCTs, which assessed a range of comparisons across different modalities (or different versions of the same modality), and as such did not provide definitive evidence for any of the possible pairwise contrasts they evaluated.

## **Adverse Events of Testing**

The evidence is insufficient for adverse events. Information on harms was often incomplete and poorly reported. Only a minority of the included studies provided information on test-related harms, raising concerns about selective outcome and analysis reporting. The majority of the studies providing information on adverse events did not report the definitions or ascertainment methods they used. Importantly, no information was available from studies meeting our selection criteria regarding the effects of ionizing radiation. Information was particularly limited on fetal and maternal outcomes of various diagnostic modalities applied during pregnancy for the investigation of acute appendicitis.

Modification of test performance										
All factors	Insufficient	Intermediate or high	Typically imprecise	Indirect (meta-regression)	Not possible to assess consistency on the basis of available data (assessments relied on cross-study comparisons)	The evidence on the effect of patient- and test-related characteristics on test performance was limited and exclusively derived from indirect comparisons. There were indications that aspects of study design characteristics affect test performance but the effects are often unpredictable in direction and do not have direct clinical relevance.				

CT = computed tomography; MRI = magnetic resonance imaging; PAS = Pediatric Appendicitis Score; Sens = sensitivity; Spec = specificity; US = ultrasound; WBC = white blood cell

Ratings reflect our trust in the estimates of test performance (from individual studies or meta-analyses) and should not be construed as clinical recommendations.

## Limitations of the Evidence Base

The evidence base regarding the diagnosis of acute appendicitis is limited in the following ways:

- *Studies reporting information on test performance outcomes were at moderate to high risk of bias.* Differential verification (the use of a different reference standard test depending on the results of the index test) and partial verification (the failure to apply the reference standard on the included patients) were common, particularly in studies that were not surgical series (generally, studies with a lower prevalence of appendicitis). Studies with complete and non-differential verification tended to be surgical cohorts reporting exclusively on patients undergoing appendectomy that are not representative of all patients with acute RLQ pain. In addition, poor reporting of information on study design hampered our risk of bias assessment.
- *Studies provided limited information to assess the impact of various patient-, technical implementation-, operator-, or system-related factors on the test performance of the tests of interest.* For example, the impact of patient age, sex, contrast use (for CT), operator experience, and setting of care on test performance and patient-relevant outcomes could not be fully explored.
- *Information on the comparative effectiveness of alternative testing strategies (e.g., sequential use of tests as part of a diagnostic algorithm) with respect to test performance, patient-relevant outcomes, and resource use was limited.* Direct (within study) comparisons of test performance and impact of testing strategies on clinical outcomes were scarce. Studies have not compared diagnostic algorithms (e.g., combinations of tests applied in sequence such that the results of earlier tests determine the choice of subsequent tests). When two or more index tests were evaluated in the same study, the role of testing that was being examined (add-on, replacement, triage) was often unclear.
- *In studies of diagnostic scores, multivariable models were often developed and evaluated in the same patient sample.* The lack of separation between the training and testing datasets (or any attempt at internal validation of the model) generally leads to optimistic (too high) estimates of test performance. The lack of external validation (replication) also limited our ability to assess the generalizability of many diagnostic scores.
- *Few RCTs compared alternative test strategies with respect to patient-relevant outcomes.* The few trials reporting patient-relevant outcomes were fragmented across heterogeneous comparisons of alternative testing strategies. The trials often used suboptimal methods for randomized sequence generation, allocation concealment, and blinding, or they provided information that was too limited to assess these aspects of study design. Many had sample sizes that were too small to reliably detect small or moderate differences between the strategies being compared.
- *In contrast to the RCTs, NRCSSs of alternative testing strategies attained large sample sizes but often reported unadjusted analyses (or analyses adjusted only for a small number of potential confounders) that do not allow drawing strong conclusions about the comparative effectiveness of alternative test strategies.*

## Strengths and Limitations of This Review

Previous reviews on this topic have focused on special patients populations (e.g., children only or pregnant women only), have largely focused on test performance outcomes, have not

assessed harms systematically, or have focused on a very limited spectrum of study designs (e.g., comparative prospective cohort studies only). Our work provides a comprehensive, up-to-date summary of the evidence on the diagnosis of RLQ pain and suspected acute appendicitis. For many of the examined tests and patient populations, this review is the first to be conducted; for some important modalities that have been to some extent investigated in previous meta-analyses (e.g., CT, MRI, US, and multivariable diagnostic scores), our work includes a much larger number of studies (and a greater total number of patients) compared to previous reviews. This allows us to provide accurate estimates of test performance in different patient populations that can be used to inform clinical decisions (especially if used as inputs in decision and simulation modeling studies) and to identify evidence gaps to inform the planning of future research.

Nonetheless, several limitations—which to some extent reflect the limitations of the underlying evidence base—need to be considered when interpreting our results. The body of evidence consisted of studies that we deemed to be of moderate to high risk of bias on the basis of aspects of their design and conduct. In some cases, methodological shortcomings and poor reporting limited our ability to draw strong conclusions, despite the availability of a large number of relevant studies.

Information for several outcomes of interest was not reported from all available studies. We were most concerned about selective outcome and analysis reporting for patient-relevant outcomes and harms. Furthermore, the selective publication of favorable or unfavorable evidence on any given test (i.e., publication bias) may have affected our results. Statistical methods for the detection of publication bias have general limitations that limit their usefulness; empirical studies in diagnostic test meta-analyses have demonstrated that existing methods are inadequate.

Information on study- or population-level characteristics that could be modifiers of test performance, patient-relevant outcomes, and adverse events was incomplete or poorly reported in the included studies. Thus, our ability to explore between-study heterogeneity using meta-regression was limited. Furthermore, because we relied on published information and did not obtain individual patient data from any of the included studies, we were unable to evaluate the impact of patient- or lesion-level factors on outcomes of interest. Although worthwhile, individual patient meta-analysis of diagnostic studies in acute appendicitis would be very challenging to undertake given the large number of available studies, each reporting findings for different test modalities, and employing alternative definitions of positive index and reference standard tests.

The reference standard in the reviewed studies was a combination of pathologic examination following appendectomy (for index test positive patients) and clinical followup (for index test negative patients); in many studies a substantial proportion of included patients were not assessed with a reference standard. Differential and incomplete verification can bias the estimation of test performance measures.

We assumed that pathological diagnosis and clinical followup have negligible measurement error (i.e., that they represent a “gold” standard). It is unlikely that this assumption is exactly true (e.g., pathologic examination may have some diagnostic error, and clinical followup provides less than perfectly accurate information). Consequently, it is likely that estimates of test performance are biased, and the direction of this bias is hard to predict, particularly at the meta-analysis level. However, we believe that the error rate of this reference standard is low enough that its influence on our estimates is relatively small.

Finally, we did not address contextual factors (e.g., availability of equipment, trained readers) that are important determinants of the adoption of specific diagnostic strategies in particular settings.

## **Applicability of Review Findings**

In general, the existing evidence on alternative diagnostic tests for the diagnosis of acute RLQ pain and suspected acute appendicitis appears to be applicable to clinical practice in the U.S. The included studies enrolled patients representative of the age and sex distribution of patients seeking care for right lower quadrant abdominal pain in the U.S. and evidence on test performance was available for all commonly used modalities. Information on adults and children was often separately reported allowing the assessment of test performance in these patient subgroups. However, information was more limited for patients at the extremes of age (i.e., children younger than 5 years or the elderly), pregnant women, and women of reproductive age; in some cases decisions for these will have to rely on extrapolation of results from population subgroups with more available information (and thus applicability assessments are not possible). Approximately one third of the studies in this review were conducted in the U.S, and the vast majority was carried out in either the U.S. or in industrialized European or Asian countries. Care settings varied across studies and included academic and non-academic centers, and patient populations were sampled at emergency departments, from surgical cohorts, or from mixed populations.

Assessing the applicability of studies on clinical symptoms and signs was challenging: the pathophysiologic rationale for many of these tests is well established. However, many of the relevant studies were conducted before the widespread availability of imaging modalities, and thus their findings may reflect test performance in a population with more advanced disease or populations selected for a high probability of appendicitis (e.g., surgical cohorts). Studies of laboratory and imaging tests evaluated “stable” technologies (e.g., white blood cell count) or had been conducted in recent years (e.g., many studies of CRP, CT, and US had been conducted from 2005 onwards). In meta-regression analyses comparing test performance in the last decade against earlier years there was no evidence that the performance of laboratory or imaging tests has changed significantly over time; however, the indirect nature of meta-regression comparisons and the low precision of meta-regression estimates limits the strength of these findings. In contrast, the applicability of the evidence on most multivariable diagnostic scores may be somewhat limited because most were developed before the era of widespread availability of imaging. The lack of external validation for most diagnostic scores also limits the applicability of these results. The findings of studies on diagnostic laparoscopy may also be less applicable because they were conducted before the widespread availability of diagnostic imaging.

## **Evidence Gaps and Ongoing Research**

Table 37 summarizes the evidence gaps with regards to the Key Questions of diagnostic test performance, patient-relevant outcomes, and adverse events.

**Table 37. Evidence gaps for the diagnosis of right lower quadrant abdominal pain and suspected acute appendicitis**

Key Question	Category	Evidence Gap
Test performance	Population	Limited information on all populations for MRI Relatively limited information on women of reproductive age, pregnant women, and the elderly for tests other than MRI
	Interventions & Comparators	Limited information on MRI Limited information on combinations of tests and alternative test algorithms
	Outcomes	Test performance outcomes (sensitivity, specificity, area under the ROC curve, etc.)
	Modifiers of test performance	Optimal imaging method for specific subgroups of patients, different presentations of patients with right lower quadrant pain, and physician- or system-level factors
Comparative test performance	Population	All populations of interest
	Interventions & Comparators	All tests of interest to this report; particularly imaging modalities in common use (CT, MRI) and emerging technologies (e.g., MRI, novel multivariable diagnostic scores) Combinations of tests, especially alternative test algorithms combining more than one tests, in sequence or in parallel
	Outcomes	Test performance outcomes (sensitivity, specificity, area under the ROC curve, etc.)
	Modifiers of test performance	Preferred imaging method for specific subgroups of patients, different presentations of patients with right lower quadrant pain, and physician- or system-level factors
Patient-centered outcomes and resource utilization	Population	All populations of interest
	Interventions & Comparators	All tests of interest to this report; particularly imaging modalities in common use (e.g., CT, MRI) and emerging technologies (e.g., MRI, novel multivariable diagnostic scores) Combinations of tests, especially alternative test algorithms combining more than one tests, in sequence or in parallel
	Outcomes	Impact on diagnostic thinking and therapeutic decisionmaking; bowel perforation (ruptured appendix), fistula formation, infectious complications (abscess formation, peritonitis, sepsis, stump appendicitis), delay in diagnosis (time from presentation to definitive diagnosis; time from presentation to initiation of treatment; time from presentation to resolution of pain), length of hospital stay, and mortality.
	Modifiers of comparative effectiveness	Information on factors that affect the incidence of adverse events is sparse. Unclear what subgroups of patients and lesions may be most likely to experience adverse events
Test-related harms	Population	All populations of interest; particularly individuals at the extremes of age and pregnant women
	Interventions & Comparators	All tests of interest to this report; particularly imaging modalities in common use (e.g., CT, MRI) and emerging technologies (e.g., MRI, new multivariable diagnostic scores) Combinations of tests, especially alternative test algorithms combining more than one tests, in sequence or in parallel
	Outcomes	Direct harms of testing (e.g., harms from exposure to ionizing radiation, allergic reactions/kidney injury caused by contrast agents); fetal/maternal outcomes (for pregnant women; including premature labor, pregnancy loss, fetal morbidity, fetal mortality, maternal morbidity, maternal mortality); harms of test-directed treatment
	Modifiers of adverse events	Limited information was available for key adverse events of interest. Reporting in existing studies was inconsistent and potentially selective. Outcome ascertainment was not standardized.

CT = computed tomography; MRI = magnetic resonance imaging; ROC = receiver operating characteristic curve;  
US = ultrasound

## Future Research Needs

### Studies of Diagnostic Test Performance

- Cohort studies of test performance would provide useful information particularly for diagnostic tests that have not been studied adequately (e.g., MRI in all relevant patient populations), and to compare the performance of tests for which comparative information is limited (e.g., direct comparisons of CT vs. US; comparisons between CT with contrast administered via alternative routes).
- Such diagnostic cohort studies (and comparative studies in particular) are also needed to evaluate the test performance of combinations of tests and testing strategies by estimating conditional test performance and by developing and validating (internally and in independent datasets) multivariable diagnostic tools. For example, they could examine the use of US as a triage test for CT or MRI, or the use of multivariable diagnostic scores to select patients who can be monitored without immediate imaging or treatment (e.g., low risk patients who can be managed with wait-and-see strategies), those who need imaging, and those who need the initiation of treatment without imaging. They can also provide information to determine how patient- and test-related factors affect performance (i.e., to examine whether test performance depends on easily identifiable patient characteristics).
- Research on the natural history of acute appendicitis, specifically on whether (and how often) cases of appendicitis can resolve on their own and the rate of recurrence among such cases is needed. Studies of natural history (e.g., among patients deemed to be appropriate candidates for medical management or wait-and-see strategies) are necessary for evaluating the impact of tests in decision and simulation modeling studies (see below) and also to inform the design of studies of alternative test-and-treatment strategies (including studies of the sequencing of multiple tests and the timing of examinations). Of note, the test performance of diagnostic tests may vary during different time-points in the development of acute appendicitis (e.g., laboratory tests may be highly sensitive for cases associated with more severe inflammation).
- Paired test study designs, in which all index tests are applied to all enrolled patients (so that each patient has results from every test of interest), are generally more efficient than parallel arm designs and should be considered when planning future studies.<sup>195</sup>
- Cohort studies assessing the performance of tests that have been evaluated extensively (e.g., CT and US) are most needed for specific patient populations (e.g., pregnant women, young children, and the elderly); for other tests (e.g., MRI) further research is needed in all patient populations. Comparative studies are needed for all tests and all populations. Ideally, future studies of test performance will be large (powered to achieve adequate precision), prospectively designed, multicenter investigations enrolling patients representative of those seen in clinical practice. Studies should prespecify the criteria for a positive test, use standardized diagnostic criteria for the diagnosis of appendicitis and use followup for an adequate period of time (1-2 weeks) for patients who do not undergo surgery, and have as complete a followup as possible. Studies that evaluate two or more index tests should provide a detailed description of the role of testing they are evaluating (triage, add-on, replacement) and report data in enough detail to allow statistical analyses appropriate for that evaluation.<sup>57</sup>

- Multivariable diagnostic scores provide an appealing way to combine information from multiple clinical symptoms and signs, laboratory tests, and (possibly) US. Multivariable scores may be particularly useful in identifying the subgroup of patients who are at low risk for appendicitis and who may be candidates for wait-and-see strategies or less aggressive imaging strategies. Cohort studies for the development and validation of such scores should use state-of-the science methods for model development and internal and external validation.
- Future research needs to be better reported and studies should adhere to established reporting guidelines (e.g., Standards for the Reporting of Diagnostic accuracy studies; [www.stard-statement.org/](http://www.stard-statement.org/)).

## **Studies of Patient-Relevant Outcomes and Resource Utilization**

- Cohort studies of diagnostic test strategies can also be used to study the impact of tests on patient-relevant and resource utilization outcomes. For tests with well-understood performance characteristics such studies may use randomized designs. For example randomized trials may be used to identify the preferred route of administration of contrast for CT scanning or to compare strategies of US triage followed by CT versus CT for all patients. In many cases, however, randomized comparisons of alternative test strategies are unlikely to be fruitful because existing studies indicate that many of the competing tests have sensitivities and specificities that are fairly similar and close to 1. Under these conditions RCTs comparing alternative test strategies would need to enroll very large numbers of participants to allow reliable comparisons. If randomized studies are deemed necessary, consideration should be given to paired randomized designs, because they are more efficient than parallel arm trials.
- Large-scale observational prospective studies could be used to evaluate the effectiveness of alternative test strategies with respect to short and long-term patient-relevant outcomes and to explore factors that may modify the effect of tests on these outcomes. Such studies would need to collect detailed information on baseline factors that may be associated with the choice of test strategy and the outcomes of interest (e.g., duration of pain, signs, symptoms and laboratory test results before imaging, patient characteristics, etc.), in order to attempt to address confounding bias. Comparisons across methods should be performed only among patients that would be candidates for assessment with all methods being compared.
- Decision and simulation modeling can be used to determine whether randomized or non-randomized cohort studies assessing patient-relevant outcomes and resource utilization are necessary and to guide their design. Models can also be used to synthesize evidence on test performance, impact of tests on clinical decisions, treatment effectiveness, resource utilization (and when relevant, economic costs), and patient preferences to guide clinical decisionmaking. We think that the results of the current review provide a solid basis for conducting such modeling studies.

## **Studies of Test-Related Adverse Events**

- *Future studies should report complete information on test-related adverse events*, using pre-specified criteria and careful ascertainment methods. Research is particularly needed

among special populations (e.g., young children, pregnant women, the elderly) and tests that have been less commonly examined (e.g., MRI with gadolinium).

- *Mathematical modeling studies can be used to combine data on the effective radiation dose received during alternative CT-based approaches (e.g., abdominopelvic vs. focused CT; low-dose vs. standard-dose CT, etc.) with external information on long-term radiation effects. Such studies appear to represent the most feasible approach to investigate the impact of testing on long-term cancer risk.*<sup>196</sup>

## Conclusions

The literature on the test performance of clinical symptoms and signs, laboratory and imaging tests, and multivariable diagnostic scores for the diagnosis of acute appendicitis is large, but consists almost exclusively of studies at moderate risk of bias (primarily due to differential and incomplete verification). The few studies that assess multiple tests are typically not designed with the goal of providing comparative information. Thus, the available evidence supports fairly strong conclusions about the performance of individual tests, but is largely insufficient to support conclusions about comparative effectiveness, especially with respect to clinical outcomes. Clinical symptoms and signs and laboratory tests have relatively limited test performance when used in isolation. Their combination in multivariable scores is promising, but the best-studied scores had been developed before the widespread use of imaging modalities and more recently developed scores have not yet been studied adequately. All three major imaging modalities have adequate test performance. Evidence on CT is mature for most patient populations of interest. In contrast, MRI has been investigated by fewer studies, many of which focus on its use for pregnant women. US produces non-diagnostic scans more often than CT or MRI, and, when a diagnosis is possible, its performance appears to be somewhat worse than CT and MRI. Beyond test performance, information on patient-relevant outcomes and resource utilization is very limited. Information on test-related harms (e.g., adverse events due to radiation) is provided only by a minority of studies and is poorly reported. More research, much of which could be accomplished through non-randomized studies, is needed to establish the performance of understudied patient populations (very young children, women of reproductive age, the elderly) and modalities (e.g., MRI, multivariable scores), compare competing tests, identify factors that affect performance, and to evaluate the impact of testing strategies on patient-relevant outcomes, resource utilization, and harms. Perhaps most importantly, given the large volume of accumulated evidence on the test performance of various tests, decision and simulation modeling (e.g., decision analysis, simulation modeling of the impact of radiation on long term outcomes) should be used to guide decisionmaking and to inform the design of future studies.

## A-2. Embase<sup>®</sup>

Because the search strategy developed for MEDLINE, initially retrieved an overwhelming number of citations, it was decided in consultation with the TEP to limit that strategy to the years 2008-present and develop a less sensitive strategy for the older articles. The two strategies are listed below.

EMBASE search 1 (more sensitive and limited to 2008-present, run 8/23/13; citations retrieved: 7200):

1. #13: #11 NOT 'case report'/de AND [humans]/lim AND [embase]/lim AND [2008-2013]/py
2. #11: #8 AND #10
3. #10: sensitivity OR specificity OR (predictive AND value) OR 'diagnosis'/exp OR (roc AND curve) OR diagnostic OR (reference AND values) OR (false AND (negative OR positive)) OR (diagnostic AND errors) OR 'accuracy'/exp OR 'screening'/exp OR 'prediction'/exp OR identify OR identification OR tests OR outcome
4. #8: #1 AND #6 and #7
5. #7: #2 OR #5
6. #6: 'accuracy'/exp OR accurate OR 'diagnosis'/exp OR diagnostic OR diagnose
7. #5: 'checklist'/exp OR 'algorithm'/exp OR (slide AND rule) OR 'calculator'/exp OR score OR scores OR (practice AND guideline) OR ('prognosis'/exp AND 'model'/exp) OR (decision AND (support AND system OR 'tree'/exp OR 'analysis'/exp OR aid OR tool OR support AND 'technique'/exp OR making)) OR 'nomogram'/exp OR 'nomograms'/exp OR (expert OR experts OR advisory AND (system OR systems)) OR (neural AND (network OR networks)) OR (artificial AND 'intelligence'/exp) OR 'machine'/exp AND 'learning'/exp OR bayes OR bayesian OR (predictive AND (value OR outcome)) OR (decision AND support AND systems) OR (diagnostic AND ('accuracy'/exp OR rule OR score OR value)) OR (clinical AND prediction) OR ('risk'/exp AND (predicton OR assesment OR score))

8. #2: 'tomography'/exp OR 'ultrasonography'/exp OR  
(magnetic AND resonance AND 'imaging'/exp) OR 'laparoscopy'/exp  
OR laparoscopic OR 'ultrasound'/exp OR 'ultra sound'/exp OR 'sonography'/exp  
OR 'mri'/exp OR 'x ray'/exp OR ('radionuclide'/exp AND 'imaging'/exp)  
OR 'radiography'/exp OR ('skin'/exp AND 'temperature'/exp) OR 'fever'/exp  
OR mcburney OR 'obturator'/exp OR psoas OR rovsing OR ('rectal'/exp AND  
(exam OR exams)) OR ('acute phase' AND 'proteins'/exp) OR  
(c AND reactive AND 'protein'/exp) OR 'crp'/exp OR 'leukocytes'/exp OR  
(acute AND phase AND 'proteins'/exp) OR ('urine'/exp AND test) OR  
(white AND 'blood'/exp AND 'cell'/exp AND count) OR 'wbc'/exp OR 'leukocyte'/exp  
OR alvarado OR mantrels
9. #1: 'appendicitis'/exp OR 'appendix'/exp OR ('abdomen'/exp AND acute)  
OR 'appendectomy'/exp OR (acute AND (abdominal OR abdominal) AND 'pain'/exp)  
OR (nonspecific OR 'non specific' OR nonAND specific AND  
(abdominal OR abdominal) AND 'pain'/exp) OR (rlq OR  
(right AND lower AND quadrant) AND 'pain'/exp) OR aap OR nsap AND [humans]/lim  
AND [embase]/lim

EMBASE search 2 (less sensitive no date limit, run 9/4/13; citations retrieved: 1213):

1. #4 #1 AND #3
2. #3 abdomen, AND acute OR 'appendicitis'/exp OR 'appendectomy'/exp OR (acute AND  
(abdome\* OR abdomi\*) AND 'pain'/exp)  
OR appendic\* OR appendec\* OR appendicec\* OR 'appendix'/exp OR (non?specificAND  
(abdome\* OR abdomi\*) AND 'pain'/exp) OR nsap OR rlq AND 'pain'/exp OR  
(right AND lower AND (quarter OR quadrant) AND 'pain'/exp) OR  
(acute AND abdominal AND 'pain'/exp) OR aap AND [humans]/lim AND [embase]/lim
3. #1 'computerized tomography'/exp OR 'computed tomography'/exp  
OR 'ct' OR enhancement\* OR 'ultrasonography'/exp OR 'sonography'/exp  
OR us OR 'ultrasound'/exp OR 'ultra sound'/exp OR ('mr'/exp  
OR magnetic AND resonance) OR 'mri'/exp OR 'magnetic resonance imaging'/exp OR  
( 'radiography'/exp OR tomography, AND 'x ray'/exp  
AND computed OR 'tomography'/exp AND scanners, AND 'x ray'/exp  
AND computed OR tomography, AND spiral AND computed) OR 'radionuclide  
imaging'/exp OR (radionuclide\* AND 'imaging'/exp)  
OR laparoscop\* OR 'laparoscopy'/exp OR 'skin'/exp AND 'temperature'/exp  
OR 'fever'/exp OR 'temperature'/exp OR (mcburney OR 'obturator'/exp  
OR psoas OR rovsing\* AND (sign OR point)) OR ('rectal'/exp AND exam\*) OR 'acute  
phase' AND 'proteins'/exp OR 'c reactive protein'/exp OR 'crp'/exp OR ('urine'/exp  
AND test OR white AND 'blood'/exp AND 'cell'/exp AND count OR 'wbc'/exp  
OR leukocyte\* OR acute AND phase AND 'proteins'/exp) OR  
(dt OR decision\* AND tools OR decision\* AND support AND system OR 'algorithm'/exp  
OR scoring AND system) OR (alvarado OR mantrels AND  
(test OR tests OR score OR scores)) AND [humans]/lim AND [embase]/lim

### A-3. Cochrane Central Register of Controlled Trials

(run 8/23/13; citations retrieved 1127)

1. (abdomen, acute OR appendicitis OR appendectomy OR appendix OR (acute AND (abdome\* OR abdomi\*) AND pain) OR appendic\* OR appendec\* OR appendicec\* OR appendix OR ( (non?specific) AND (abdome\* OR abdomi\*) AND pain) OR nsap OR RLQ pain OR (right AND lower AND (quarter OR quadrant) AND pain) OR (acute AND abdominal AND pain) OR AAP)  
AND
2. Quality Item 1 = Was a consecutive or random sample of patients enrolled?											
Quality Item 2 = Were the index test results interpreted without knowledge of the results of the reference standard?											
Quality Item 3 = If a threshold was used, was it prespecified?											
Quality Item 4 = Is the reference standard likely to correctly classify the target condition?											
Quality Item 5 = Were the reference standard results interpreted without knowledge of the results of the index test?											
Quality Item 6 = Did all patients receive a reference standard?											
Quality Item 7 = Did all patients receive the same reference standard?											
Quality Item 8 = Were all patients included in the analysis?											

**Table C3. Test performance of multivariable diagnostic scores**

Quality Item 1 = Was a consecutive or random sample of patients enrolled?

Quality Item 2 = Were the index test results interpreted without knowledge of the results of the reference standard?

Quality Item 3 = If a threshold was used, was it prespecified?

Quality Item 4 = Is the reference standard likely to correctly classify the target condition?

Quality Item 5 = Were the reference standard results interpreted without knowledge of the results of the index test?

Quality Item 6 = Did all patients receive a reference standard?

Quality Item 7 = Did all patients receive the same reference standard?

Quality Item 8 = Were all patients included in the analysis?

**Table C5. RCT study design**

Comparison of CT and routine management									
Study	Population selection criteria	Randomized interventions	Enrolment period	# centers	Power calculations?	Enrolment goal met?	Duration and method of follow-up	Loss to follow-up	Cluster trial, non-inferiority?
Hong et al. 2003 (United States) PMID: 14588157 <sup>335</sup>	Patients at least 18 years old presenting to the emergency department with a possible diagnosis of acute appendicitis and an Alvarado score of 2-8. Exclusion criteria were awaiting interval appendectomy, unable to receive IV contrast, pregnancy, or unreliable clinical exams (e.g., taking steroids, known IBD, sickle cell disease).	1) Clinical observation alone, consisting of admission to the surgical service and monitoring with serial physical examinations and laboratory studies until there is resolution of symptoms, another diagnosis is confirmed, or appendectomy is performed for high clinical suspicion. 2) Clinical observation and abdominal/ pelvic CT. CT scans performed on a helical scanner with oral and iv contrast. Scans interpreted by a senior radiology resident or a radiology attending.	November 1998 through October 1999	1	Yes	Yes	1 week phone call post discharge	19.8% (36/182) protocol violators not included in analysis and 20.9% (38/182) not reached by phone for follow-up.	No
Lee et al. 2007 (United States) PMID: 17192450 <sup>494</sup>	All patients over 18 years presenting to the emergency department with acute right lower quadrant abdominal pain (duration less than 7 hours) and suspected acute appendicitis. Exclusion criteria were pregnancy, evidence of diffuse peritonitis, a serum creatinine level greater than 1.6 mg/dL, and a history of contrast allergy.	1) The selective use of CT imaging, at the discretion of the treating physicians based on the clinical presentation. 2) Mandatory CT imaging. CT scans of the abdomen and pelvis were carried out with oral and iv contrast. Scans were interpreted by a board-certified radiologist.	January 2001 to May 31, 2004	1	Yes	Yes	Telephone call 48 hours after discharge from hospital or emergency department.	Unclear. All patients were included in analysis, however follow-up information was only available on 42% of non-operated (n=64?) patients overall	No
Lehtimäki et al. 2013 (Finland)	All patients over 18 years presenting to the surgical emergency department with	1) The selective use of CT imaging, at the discretion of the treating physicians based on the clinical	January 2009 to May 2010	1	Yes	Yes	Further examinations during 3	3.3% (10/300) did not meet inclusion	No

PMID: 23715771 <sup>505</sup>	acute abdominal pain of unknown cause lasting for more than 2 hours and less than 7 days. Exclusion criteria were pregnancy, acute abdominal trauma, previous participation in the study, patient transfer as an inpatient from elsewhere with an established diagnosis for the cause of the abdominal pain, contraindication to iodinated contrast media, and withdrawal from active treatment, and requiring immediate surgery.	presentation. 2) Mandatory CT imaging within 24 hours of admission. All CT scans were carried out on a 64-row CT system. All CT scans in the mandatory arm were carried out with iv contrast and usually without oral contrast, but could be modified by radiologist preference. In the selective imaging arm, CT could be freely modified according to the clinical question. Scans were interpreted by a board-certified radiologist.					months of follow-up	criteria or withdrew consent and 12% (36/300) were lost to follow-up.	
Lopez et al. 2007 (United States) United States PMID: 18186378 <sup>527</sup>	Female patients between 18 and 45 years presenting to the emergency room with a possible diagnosis of acute appendicitis and an Alvarado score of 2-8. Exclusion criteria were awaiting interval appendectomy, unable to receive IV contrast, and pregnancy, HIV positive status, or known IBD.	1) Clinical observation alone, consisting of admission to the surgical service and monitoring with serial physical examinations and laboratory studies until there is resolution of symptoms, another diagnosis is confirmed, or appendectomy is performed for high clinical suspicion. 2) Clinical observation and abdominal/pelvic CT. CT scans were performed on a helical scanner with oral and iv contrast. Scans interpreted by a senior radiology resident or a radiology attending.	November 1999 to February 2001 and March 2003 to December 2004	1	Yes	No	1 week phone call post discharge	2.2% (2/90) protocol violators not included in analysis and 21.1% (19/90) not reached by phone for follow-up.	No
Ng et al. 2002 (England) PMID: 12480851 (same study as Ng et al. 2007 PMID: 17329682, Ng et al. 2010 PMID: 20350244) <sup>609</sup>	All patients over 18 years presenting to the emergency room from 9 am Friday to 5 pm Sunday with acute abdominal pain and admitted under the care of the surgical team. Exclusion criteria were requiring emergency surgery or urgent CT, and pregnancy, rectal bleeding, suspected gynaecological disorders or perianal abscesses.	1) Current standard practice, including plain radiography and, if indicated, ultrasonography, computed tomography, and fluoroscopic investigations. 2) Early CT (within 24 hours of admission). Other radiological investigations during the first 24 hours were also allowed. CT scans were performed on a helical scanner with oral, rectal, and contrast medium and pump injection. Scans	October 1999 to September 2000	1	Yes	Yes	Patients' notes reviewed 6 months after admission	1.7% (2/120) protocol violators not included in analysis	No

		reported by the on-call radiologist.							
Ng et al. 2007 (England) PMID: 17329682 (same study as Ng et al. 2002 PMID: 12480851, Ng et al. 2010 PMID: 20350244) <sup>607</sup>	All patients over 18 years presenting to the emergency room from 9 am Friday to 5 pm Sunday with acute abdominal pain and admitted under the care of the surgical team. Exclusion criteria were requiring emergency surgery or urgent CT, and pregnancy, rectal bleeding, suspected gynaecological disorders or perianal abscesses.	1) Current standard practice, including plain radiography and, if indicated, ultrasonography, computed tomography, and fluoroscopic investigations. 2) Early CT (within 24 hours of admission). Other radiological investigations during the first 24 hours were also allowed. CT scans were performed on a helical scanner with oral, rectal, and contrast medium and pump injection. Scans reported by the on-call radiologist.	October 1999 to September 2000	1	Yes	Yes	Patients' notes reviewed 6 months after admission	1.7% (2/120) protocol violators not included in analysis	No
Ng et al. 2010 (England) PMID: 20350244 (same study as Ng et al. 2002 PMID: 12480851, Ng et al. 2007 PMID: 17329682) <sup>608</sup>	All patients over 18 years presenting to the emergency room from 9 am Friday to 5 pm Sunday with acute abdominal pain and admitted under the care of the surgical team. Exclusion criteria were requiring emergency surgery or urgent CT, and pregnancy, rectal bleeding, suspected gynaecological disorders or perianal abscesses.	1) Current standard practice, including plain radiography and, if indicated, ultrasonography, computed tomography, and fluoroscopic investigations. 2) Early CT (within 24 hours of admission). Other radiological investigations during the first 24 hours were also allowed. CT scans were performed on a helical scanner with oral, rectal, and contrast medium and pump injection. Scans reported by the on-call radiologist.	October 1999 to September 2000	1	Yes	Yes	Patients' notes reviewed 6 months after admission	1.7% (2/120) protocol violators not included in analysis	No
Sala et al. 2009 PMID: 17901913 <sup>734</sup>	All patients over 18 years presenting to the on-call general surgeons between 9 a.m. and 9 p.m. with a diagnosis of nonspecific acute abdominal pain, either following self-referral to the A&E or following referral by their GP. Exclusions were pregnancy, presenting complaint of rectal bleeding, suspected renal colic, suspected gynaecological disorders, or need for urgent CT or emergency surgery.	1) Current standard practice, which comprised plain radiography of the supine abdomen and erect chest. Patients were not denied access to CT if it was subsequently deemed necessary 2) Early CT (within 1 hour of presentation). CT scans from the diaphragm to the symphysis pubis were performed on a 16 detector scanner with iv contrast. Scans were reported by the CT on-call radiologist.	February 2004 to July 2004	1	Yes	Yes	Patient's medical records reviewed at 6 months.	3.4% (3/205) protocol violators not included in analysis, 3/205 patients randomized twice (only data from the first presentation were included), and 1/205 patients	No

								with medical records not available at 6 months)	
Walker et al. 2000 (United States) PMID: 11182396 <sup>868</sup>	All patients over 18 years receiving general surgery consultation for appendicitis at the emergency department. Exclusion criteria were pregnancy, contraindication to rectal contrast material, and patients who had an appendiceal ultrasound performed prior to general surgical evaluation.	1) Standard management which varied from observation with serial abdominal examinations to right lower quadrant ultrasound, to immediate operation. CT scans with oral or IV contrast, or both, were allowed. 2) Limited CT scan with colorectal contrast. The randomized CT scan group patients received focused, helical, appendiceal CT. A staff radiologist read the CT scan. A single radiologist performed blinded, retrospective over-reads of all CT scans.	July 1998 to June 1999	1	No	N/A	Follow-up telephone call mentioned but timing not reported.	None	No

Farahnak et al. 2007 (Iran) PMID: 17870498 <sup>238</sup>	All consecutive patients over 6 years initially admitted to the emergency service for abdominal pain. Exclusion criteria were: evidence of generalized peritonitis; suspicion of abdominal mass or abdominal involvement of degenerative or systemic disease; evidence of mental disturbances, acute confusional state, or dementia; or had already had any imaging including plain radiography, US or CT.	1) Standard clinical assessment and management 2) Management according to Alvarado score Management according to Alvarado score consisted of division into subgroups according to scores of 4 or less, 5-7, or 8-10. Patients with scores of 4 or less received discharge and no followup. Patients with scores of 8-10 received immediate operation after IV injection of antibiotics. Patients with scores of 5-7 received IV antibiotics and an outpatient prescription for antibiotics. They were asked to attend 1 day in the clinic.	September 1 2005 to December 15 2005	1	No	N/A	NR	None	No
Lintula et al. 2009 (Finland) PMID: 18841382 <sup>523</sup>	Children aged 4-15 years presenting at the Emergency Department with suspected acute appendicitis. The diagnostic criteria for acute appendicitis were those set by the World Organization of Gastroenterology Research Committee. Exclusion criteria were a history of previous appendectomy, and abdominal trauma or hernia.	1) Standard clinical assessment and management 2) Management according to a diagnostic scoring system for children. The diagnostic scoring system was constructed and validated by the authors in a previous study. The score included nine variables and ranged from 0 to 32 points. A score of 15 or less corresponded to low probability of appendicitis (amenable to discharge), a score of 16-20 corresponded to intermediate probability of appendicitis (necessitating further observation), and a score of 21 or greater corresponded to high probability of appendicitis (justifying emergency appendectomy). Children with positive abdominal guarding or	January 2005 and January 2007	1	No, only post hoc	N/A	Telephone call at 4 weeks.	None	No

		rebound test were recommended to be observed/operated on, even if the sum of the appendicitis score was 15 or less. The diagnostic guidelines of the appendicitis score were not followed strictly. No imaging studies were used in the trial.							
Lintula et al. 2010 (Finland) PMID: 20379739 <sup>524</sup>	Patients age 16 and above presenting at the Emergency Department with suspected acute appendicitis. Exclusion criteria were a history of previous appendectomies, abdominal trauma, hernia or chronic abdominal pathology, or other intra-abdominal pathology requiring emergency laparotomy.	1) Standard clinical assessment and management 2) Management according to a diagnostic scoring system for children, now applied in adults. The diagnostic scoring system was constructed and validated by the authors in a previous study. The score included nine variables and ranged from 0 to 32 points. A score of 15 or less corresponded to low probability of appendicitis (amenable to discharge), a score of 16-20 corresponded to intermediate probability of appendicitis (necessitating further observation), and a score of 21 or greater corresponded to high probability of appendicitis (justifying emergency appendectomy).	January 2005 and January 2007	1	Yes	Yes	Telephone call at 4 weeks	2.2% (4/181) (one in the score group and three in the no score group were excluded because they required imaging studies to exclude other intra-abdominal surgical pathologies)	No

# Appendix F. Risk of Bias Assessment for Studies of Test Performance

**Table F1. Risk of bias assessment for studies of test performance**

Variable	Definitions
Extractor 1	Extractor initials
study_author	First author in the publication
study_year	Year of publication
study_pmid	PMID of the publication If single publication reports multiple studies (eg. Retrospective and prospective cohorts with complete information), complete separate risk of bias row for each, labeled pmid_a, pmid_b ...
Was a consecutive or random sample of patients enrolled?	Do the authors state that (1) patients were enrolled consecutively? OR (2) Discuss a random sampling scheme for selecting patients for inclusion?
Was a case-control design avoided?	Did the study enroll preferentially affected and unaffected individuals?  In most cases this should be “YES”, because of our selection criteria. Occasionally we should expect some “UNCLEAR”
Did the study avoid inappropriate exclusions?	Where more than 10% of enrolled patients excluded for any reason other than unavailability of index test results?  YES: <=10% of enrolled patients were excluded for reasons other than the unavailability of index test results YES: >10% of enrolled patients were excluded for reasons other than the unavailability of index test results UNCLEAR: we cannot distinguish between the above two categories (includes cases where data on the % excluded are not reported, or cases where the reasons for exclusion are not reported and the total proportion of excluded patients is >10%. If the total % excluded is <10% - even if reasons are not reported – the study gets a “YES”).
Were the index test results interpreted without knowledge of the results of the reference standard?	Where index test assessors blinded to the reference standard results?  YES: blinding is explicitly mentioned, or the authors clearly describe a process by which index test results were “called” before reference standard results were available NO: explicitly states or can confidently infer that no blinding of index test assessors was in place UNCLEAR: not reported or not enough information to be certain
If a threshold was used, was it prespecified?	Was the criterion for positive index test results defined a priori? E.g. is it stated that it was determined in the study protocol? Is it stated that it was determined based on the literature?  YES: a priori determined (protocol, literature-based, prior studies) NO: clearly determined using data from the same study (e.g., determined via ROC analysis) UNCLEAR: not reported or not enough information to be certain
Is the reference standard likely to correctly classify the target condition?	Was the reference standard pathology OR followup of 14 days or more for 90% of the analyzed population?  YES: >=90% or more of analyzed patients had pathology OR 14-day (or longer) followup

	<p>NO: &lt;90% of patients had pathology OR 14-day (or longer) followup  UNCLEAR: not reported or not enough information to be certain</p>
<b>Were the reference standard results interpreted without knowledge of the results of the index test?</b>	<p>Where reference standard test assessors blinded to the index test results?</p> <p>YES: blinding is explicitly mentioned, or the authors clearly describe a process by which reference standard test results were “called” with no knowledge of index test results  NO: explicitly states or can confidently infer that no blinding of reference standard test assessors was in place  UNCLEAR: not reported or not enough information to be certain</p>
<b>Was there an appropriate interval between index tests and reference standard?</b>	<p>If pathology was used on all patients: enter NOT APPLICABLE</p> <p>If followup was used as the reference standard at least for sum patients, was is &gt;14 days?</p> <p>YES: followup was available for 14-days or more on &gt;=90% of patients  NO: followup was less than 14-days for &gt;10% of patients  UNCLEAR: not reported or not enough information to be certain</p> <p>Note: this variable will be correlated strongly with the “appropriateness of ref. standard” question.</p>
<b>Did all patients receive a reference standard?</b>	<p>Was <u>any acceptable</u> reference standard test used for &gt;=90% of patients?</p> <p>YES: &gt;= 90% of patients used an acceptable reference standard (pathology OR followup of any duration)  NO: &lt;90% of patients used an acceptable reference standard  UNCLEAR: not reported or not enough information to be certain</p>
<b>Did all patients receive the same reference standard?</b>	<p>Was <u>the same reference</u> standard test used for &gt;=90% of patients?</p> <p>YES: &gt;= 90% had pathology as the reference standard  YES: &gt;= 90% had followup of any duration as the reference standard  NO: &lt;90% of patients used the same reference standard (all other cases where the proportion is reported and is &lt;90% for each of the reference standards used)  UNCLEAR: not reported or not enough information to be certain</p>
<b>Were all patients included in the analysis?</b>	<p>Was the percentage of patients included in the analysis &gt;=90% of the patients enrolled in the study?</p> <p>YES: &gt;= 90% of patients enrolled were analyzed (i.e., in 2x2 table)  NO: &lt;90% of patients enrolled were analyzed (i.e., in 2x2 table)  UNCLEAR: not reported or not enough information to be certain</p>
